OPERATIVE TECHNIQUES IN ORTHOPAEDIC SURGERY

Sam W. Wiesel, MD
EDITOR-IN-CHIEF
Professor and Chair
Department of Orthopaedic Surgery
Georgetown University Medical School
Washington, DC

VOLUME ONE
For Barbara Wiesel—confidante, advisor, best friend, and wife—thank you for a wonderful 39 years. With much love.

SWW
Dedication

To my beloved and inspiring family: Shelly, Yarden, Tom, Nimrod, and Dan —JB

To my family for the unending support of my academic endeavors. —SDB

To my orthopaedic mentors, especially Ed Hanley, John Hall, Jim Kasser, and Peter Waters, who have inspired me to write and teach and give back to orthopaedics, the way they have. —JMF

To Drs. Kenneth C. Francis, Ralph Marcove, and William F. Enneking, three great innovators, pioneers, developers, and critical thinkers in the field of orthopaedic oncology. I had the privilege to work with all three great pioneers and dedicate my work on this project to these world-class surgeons. —MMM

To my last child to leave the nest, Missy. I hope that all of our time together can be “quality time.” —Your loving father, MDM

To my beautiful wife, Fariba, for her fortitude, devotion, and love. —JP

To my dear wife, Marcia, for always believing in and supporting me; to my children, Julia and James, for being my inspirations; to my parents, for always providing for me; and to God, for making it all possible. —JMR

To my mother, Phyllis, who found the best in people, had compassion for all, and whose insight, guidance, and love have always made me believe that anything is possible. —PT

To our wives, Robin and Nancy, and our children, Mark and Alexis and Chelsea, Alex, and Julia. —GRW and MLR

To my wife, Mary Lynne, and my children, Ford, Benson, and Charlotte, for patiently tolerating the time I spent away from them while I pursued this academic endeavor, and to my parents, Barbara and Dennis Easley, whose guidance and support prepared me for a career in academic medicine. —MEE

To my cherished wife Teri and our four extraordinary children, Thomas, William, Caitlin, and Christopher, for their love and understanding, and especially for their endless supply of smiles, laughter, and fun!—TRH
Volume One

PART 1 SPORTS MEDICINE

SECTION I SHOULDER

1 Shoulder Arthroscopy: The Basics
   Elizabeth Matzkin and Craig R. Bottoni 7

2 Arthroscopic Treatment of Anterior Shoulder Instability
   Robert A. Arciero, Augustus D. Mazzocca, and Jeffrey T. Spang 14

3 Arthroscopic Treatment of Posterior Shoulder Instability
   Fotios P. Tjoumakaris and James P. Bradley 24

4 Arthroscopic Treatment of Multidirectional Shoulder Instability
   Steven B. Cohen and Jon K. Sekiya 30

5 Arthroscopic Treatment of Superior Labral (SLAP) Tears
   Brian Cole and John-Paul Rue 38

6 Management of Shoulder Throwing Injuries
   Matthew T. Boes and Craig D. Morgan 44

7 Arthroscopic Treatment of Biceps Tendonopathy
   J. R. Rudzki and Benjamin S. Shaffer 57

8 Arthroscopic Treatment of Subacromial Impingement
   R. Timothy Greene and Spero G. Karas 68

9 Acromioclavicular Disorders
   R. Timothy Greene and Spero G. Karas 75

10 Arthroscopic Treatment of Rotator Cuff Tears
    Robert Z. Tashjian, Jay D. Keener, and Ken Yamaguchi 81

11 Arthroscopic Treatment of Subscapularis Tears, Including Coracoid Impingement
    Christopher R. Adams and Stephen S. Burkhart 91

12 Repair and Reconstruction of Acromioclavicular Injuries
   Amir Mostofi, Augustus D. Mazzocca, and Robert A. Arciero 102

13 Arthroscopic Acromioclavicular Joint Reduction and Coracoclavicular Stabilization: TightRope Fixation
   Michael S. Todd and Winston J. Warme 116

14 Arthroscopic Release of Nerve Entrapment
   Felix H. Savoie, III, and Larry D. Field 122

15 Arthroscopic Capsular Releases for Loss of Motion
   Ryan W. Simovitch, Laurence D. Higgins, and Jon J.P. Warner 125

16 Arthroscopic Treatment of Scapulothoracic Disorders
   Michael J. Huang and Peter J. Millett 134

17 Arthroscopic Débridement and Glenoidplasty for Shoulder Degenerative Joint Disease
   Christian J. H. Veillette and Scott P. Steinmann 138

SECTION II ELBOW

18 Elbow Arthroscopy: The Basics
   John E. Conway 145

19 Arthroscopic Treatment of Chondral Injuries and Osteochondritis Dissecans
   Marc Safran 155

20 Arthroscopic Treatment of Valgus Extension Overload
   Sami O. Khan and Larry D. Field 166

21 Arthroscopic Treatment of Elbow Loss of Motion
   Matthew T. Provencher, Mark S. Cohen, and Anthony A. Romeo 171

22 Arthroscopic Débridement for Elbow Degenerative Joint Disease
   Julie E. Adams and Scott P. Steinmann 179

23 Arthroscopic Treatment of Epicondylitis
   Kevin P. Murphy, Jeffrey R. Giuliani, and Brett A. Freedman 184

SECTION III HIP

24 Hip Arthroscopy: The Basics
   Marc Safran and Matthew A. Stanich 191

25 Arthroscopy for Soft Tissue Pathology of the Hip
   J. W. Thomas Byrd and MaCalus V. Hogan 203

26 Arthroscopic Management of Femoroacetabular Impingement
   Christopher M. Larson and Rebecca M. Stone 213

27 Snapping Hip
   J. W. Thomas Byrd and MaCalus V. Hogan 222

28 Athletic Pubalgia
   Jesse C. Botker, Robert F. LaPrade, and David R. Joesting 231

29 Adductor Longus–Related Groin Pain
   Robert T. Sullivan and William E. Garrett 238

30 Proximal Hamstring Injury
   Robert T. Sullivan and William E. Garrett 243

SECTION IV KNEE

31 Knee Arthroscopy: The Basics
   Steven A. Aviles and Christina R. Allen 248

SECTION III LEG

15 External Fixation of the Tibia
J. Tracy Watson 629

16 Intramedullary Nailing of the Tibia
Mark A. Lee and Brett D. Crist 642

17 Fasciotomy of the Leg for Acute Compartment Syndrome
George Partal, Andrew Furey, and Robert O’Toole 660

SECTION IV FOOT AND ANKLE

18 Open Reduction and Internal Fixation of the Pilon
Cory A. Collinge and Michael Prayson 671

19 Open Reduction and Internal Fixation of the Ankle
Kenneth A. Egol 687

20 Open Reduction and Internal Fixation of the Talus
David E. Karges 697

21 Surgical Treatment of Calcaneal Fractures
James B. Carr 712

22 Open Reduction and Internal Fixation of Lisfranc Injury
Michael P. Clare and Roy W. Sanders 724

23 Open Reduction and Internal Fixation of Jones Fracture
William R. Creevy and Seth P. Levitz 734

PART 3 ADULT RECONSTRUCTION

SECTION I HIP RECONSTRUCTION

1 Cemented Total Hip Arthroplasty
Matthew S. Hepinstall and José A. Rodriguez 744

2 Uncemented Total Hip Arthroplasty
Matthew S. Austin and Brian A. Klatt 756

3 Hip Resurfacing 763
Kang-Il Kim and Ameet Pispati

4 Hemiarthroplasty of the Hip
Hari P. Bezwada, Robert H. Cho, and David G. Nazarian 782

5 Total Hip Arthroplasty for Malignant Lesions
R. Lor Randall 798

6 Revision Total Hip Arthroplasty With Well-Fixed Components
Trevor R. Pickering and Michael E. Berend 808

7 Revision Total Hip Arthroplasty With Femoral Bone Loss: Fluted Stems
Christian P. Christensen and Cale A. Jacobs 815

8 Revision Total Hip Arthroplasty With Femoral Bone Loss: Proximal Femoral Replacement
Javad Parvizi, Benjamin Bender, and Franklin H. Sim 823

9 Revision Total Hip Arthroplasty With Acetabular Bone Loss: Impaction Allografting
Gregg R. Klein, Harlan B. Levine, and Mark A. Hartzband 831

10 Revision Total Hip Arthroplasty With Acetabular Bone Loss: Antiprotrusio Cage
Matthew S. Austin, James J. Purtill, and Brian A. Klatt 836

11 Resection Arthroplasty and Spacer Insertion
Mark J. Spangehl and Christopher P. Beauchamp 843

12 Hip Reimplantation Surgery
Nelson V. Greidanus, Winston Y. Kim, and Bassam A. Masri 853

SECTION II HIP PRESERVATION

13 Periacetabular Osteotomy
Marco Teloken, David Gusmao, and Marcus Crestani 859

14 Femoral Osteotomy
Philipp Henle, Moritz Tannast, and Klaus A. Siebenrock 869

15 Femoroacetabular Impingement and Surgical Dislocation of the Hip
Martin Beck and Michael Leunig 877

16 Treatment of Anterior Femoroacetabular Impingement Through an Anterior Incision
John C. Clohisy 887

SECTION III KNEE RECONSTRUCTION

17 Unicondylar Knee Arthroplasty
Keith R. Berend, Jeffrey W. Salin, and Adolph V. Lombardi Jr. 895

18 Upper Tibial Osteotomy
James Bicos and Robert A. Arciero 905

19 Cemented Total Knee Arthroplasty
S. Mehdi Jafari and Javad Parvizi 918

20 Total Knee Arthroplasty Using Navigation
William J. Hozack, S. M. Javad Mortazavi, and Camilo Restrepo 933

21 Revision Total Knee Arthroplasty With Femoral Bone Loss: Metal Augments
Gwo-Chin Lee 942

22 Revision Total Knee Arthroplasty With Tibial Bone Loss: Metal Augments
Shawn M. Brubaker, William Mihalko, Thomas E. Brown, and Khaled J. Saleh 949

23 Revision Total Knee Arthroplasty With Femoral Bone Loss: Distal Femoral Replacement
B. Sonny Bal 962

24 Revision Total Knee Arthroplasty With Tibial Bone Loss: Bone Grafting
Brian Vannozzi, Gwo-Chin Lee, and Jonathan Garino 969

25 Revision Total Knee Arthroplasty With Removal of Well-fixed Components
Matthew S. Austin, S. Mehdi Jafari, and Benjamin Bender 975

26 Revision Total Knee Arthroplasty With Extensile Exposure: Tibial Tubercle Osteotomy
Anish K. Amin and James T. Patton 980

27 Revision Total Knee Arthroplasty With Extensile Exposure: V-Y Quadroplasty
Ali Oliashirazi 986

28 Revision Total Knee Arthroplasty With Extensor Mechanism Repair
Fabio Orozco and Alvin Ong 989
Volume Two

PART 4 PEDIATRICS

SECTION I TRAUMA

1 Intramedullary Fixation of Forearm Shaft Fractures
   Charles T. Mehlman 1026

2 Open Reduction and Internal Fixation of Displaced Lateral Condyle Fractures of the Humerus
   Kristan A. Pierz and Brian G. Smith 1035

3 Open Reduction and Internal Fixation of Fractures of the Medial Epicondyle
   Brian G. Smith and Kristan A. Pierz 1042

4 Open Reduction of Supracondylar Fractures of the Humerus
   Jennifer J. Winell and John M. Flynn 1046

5 Closed Reduction and Percutaneous Pinning of Supracondylar Fractures of the Humerus
   Paul D. Choi and David L. Skaggs 1050

6 Closed, Percutaneous, and Open Reduction of Radial Head and Neck Fractures
   Jenny M. Frances and Roger Cornwall 1058

7 Percutaneous Joystick and Intramedullary Reduction (Metaizeau) Techniques for Radial Neck Fractures
   Unni G. Narayanan and Fabio Ferri-De-Barros 1066

8 Supracondylar Humeral Osteotomy for Correction of Cubitus Varus
   Yi-Meng Yen, Richard E. Bowen, and Norman Y. Otsuka 1075

9 Pediatric Shoulder Fractures
   Craig P. Eberson 1080

10 Pediatric Hip Fractures
    R. Dale Blasier 1088

11 Closed Reduction and Spica Casting of Femur Fractures
    Matthew R. Garner and John M. Flynn 1095

12 Closed Reduction and External Fixation of Femoral Shaft Fractures
    Stuart M. Myers and John M. Flynn 1099

13 Flexible Intramedullary Nailing of Femoral Shaft Fractures
    Gilbert Chan and John M. Flynn 1106

14 Submuscular Plating of Femoral Shaft Fractures
    Ernest L. Sink 1111

15 Distal Femoral Physeal Fractures
    R. Dale Blasier 1116

16 Pediatric Tibial Fractures
    Craig P. Eberson 1122

17 Open Reduction and Internal Fixation of Tibial Tuberosity Fractures
    Ernest L. Sink 1130

18 Operative Management of Pediatric Ankle Fractures
    Bryan T. Leek and Scott J. Mubarak 1134

SECTION II ARTHROSCOPIC AND SPORTS MEDICINE

19 Elbow Arthroscopy for Panner’s Disease and Osteochondritis Dissecans
   Theodore J. Ganley, Gilbert Chan, Aaron B. Heath, and J. Todd R. Lawrence 1144

20 Patellar Instability
   Eric J. Wall and James R. Romanowski 1149

21 Proximal Patellar Realignment
   Jay C. Albright 1156

22 Arthroscopy-Assisted Management or Open Reduction and Internal Fixation of Tibial Spine Fractures
   Gilbert Chan and Lawrence Wells 1161

23 Anterior Cruciate Ligament Reconstruction in the Skeletally Immature Patient
   J. Todd R. Lawrence and Mininder S. Kocher 1168

24 Arthroscopic Drilling of Osteochondritis Dissecans
   Theodore J. Ganley, Gilbert Chan, and Aaron B. Heath 1177

25 Meniscoplasty for Discoid Lateral Meniscus
   Jay C. Albright 1183

SECTION III RECONSTRUCTION

26 Proximal Femoral Rotational Osteotomy
   Unni G. Narayanan 1187

27 Proximal Femoral Varus Osteotomy Using a 90-Degree Blade Plate
   Tom F. Novacheck 1196

28 Treatment of Congenital Femoral Deficiency
   Dror Paley and Shawn C. Standard 1202

29 Surgical Repair of Irreducible Congenital Dislocation of the Knee
   Matthew B. Dobbs, Noppachart Limpaphayom, and J. Eric Gordon 1224

30 Surgical Management of Blount’s Disease
   Eric D. Shirley and Richard S. Davidson 1230

31 Percutaneous Distal Femoral or Proximal Tibial Epiphysiodesis
   J. Richard Bowen 1238

32 Excision of Physeal Bar
   Anthony A. Stans 1244

33 Repair of Congenital Pseudarthrosis of the Tibia With the Williams Rod
   Perry L. Schoenecker and Margaret M. Rich 1251
CONTENTS

34 Limb Lengthening Using the Ilizarov Method or a Monoplanar Fixator
Roger F. Widmann, Purushottam A. Gholve, and Arkady Blyakher 1258

35 Guided Growth to Correct Limb Deformity
Peter M. Stevens 1270

36 Distal Tibial Osteotomy
Kathryn A. Keeler and J. Eric Gordon 1276

37 Multiple Percutaneous Osteotomies and Fassier-Duval Telescoping Nailing of Long Bones in Osteogenesis Imperfecta
Paul W. Esposito 1284

38 Syme and Boyd Amputations for Fibular Deficiency
Anthony A. Scaduto and Robert M. Bernstein 1295

39 Hemi-Epiphysiodesis for Ankle Valgus
Peter M. Stevens 1304

SECTION IV NEUROMUSCULAR CORRECTION

40 Adductor and Iliopsoas Release
Tom F. Novacheck 1310

41 Rectus Femoris Transfer
Jon R. Davids 1316

42 Proximal Hamstring and Adductor Lengthening
Freeman Miller and Kirk W. Dabney 1322

43 Distal Hamstring Lengthening
Jon R. Davids 1326

44 Gastrocnemius Fascia Lengthening
James J. McCarthy and David A. Spiegel 1334

45 Distal Femoral Osteotomy for Crouch Gait
Tom F. Novacheck 1339

SECTION V CYSTS

46 Benign Bone Cysts
Alexandre Arkader and John P. Dormans 1345

SECTION VI UPPER EXTREMITY

47 Release of Simple Syndactyly
Donald S. Bae 1351

48 Correction of Thumb-in-Palm Deformity in Cerebral Palsy
Thanapong Waitayawinyu and Scott N. Oishi 1358

49 Release of the A1 Pulley to Correct Congenital Trigger Thumb
Roger Cornwall 1366

50 Transfer of Flexor Carpi Ulnaris for Wrist Flexion Deformity
Ann E. Van Heest 1371

51 Radial Dysplasia Reconstruction
Scott N. Oishi and Marybeth Ezaki 1376

52 Forearm Osteotomy for Multiple Hereditary Exostoses
Carla Baldrighi and Scott N. Oishi 1380

53 Modified Woodward Repair of Sprengel Deformity
J. Richard Bowen 1387

SECTION VII SPINE

54 Release of the Sternocleidomastoid Muscle
Gokce Mik and Denis S. Drummond 1392

55 Posterior Cervical Arthrodeses: Occiput–C2 and C1–C2
John P. Dormans, Gokce Mik, and Purushottam A. Gholve 1399

56 Posterior Exposure of the Thoracic and Lumbar Spine
James T. Guille and Reginald S. Fayssoux 1408

57 Segmental Hook and Pedicle Screw Instrumentation for Scoliosis
James T. Guille and Reginald S. Fayssoux 1414

58 Kyphectomy in Spina Bifida
Richard E. McCarthy 1424

59 Anterior Interbody Arthrodesis With Instrumentation for Scoliosis
Daniel J. Sucato 1431

60 Thoracoscopic Release and Fusion for Scoliosis
Daniel J. Sucato 1442

61 Unit Rod Instrumentation for Neuromuscular Scoliosis
Kirk W. Dabney and Freeman Miller 1448

62 Growing Rod Instrumentation for Early-Onset Scoliosis
Victor Hsu and Behroz Akbarnia 1458

63 Hemivertebra Excision 1466
Daniel J. Hedequist and John B. Emans

64 Posterolateral Arthrodesis for Spondylolisthesis
James T. Guille and Reginald S. Fayssoux 1474

65 Decompression, Posterolateral, and Interbody Fusion for High-Grade Spondylolisthesis
Gilbert Chan and John P. Dormans 1480

66 S-Rod Fixation to the Pelvis
Richard E. McCarthy 1489

SECTION VIII HIP

67 Anterior Approach for Open Reduction of the Developmentally Dislocated Hip
Richard M. Schwend 1493

68 Medial Approach for Open Reduction of a Developmentally Dislocated Hip
Lori A. Karol and Jeffrey E. Martus 1502

69 Anterior Drainage of the Septic Hip in Children
Richard M. Schwend 1508

70 Innominate Osteotomy of Salter
Richard E. Bowen and Norman Y. Otsuka 1517

71 Periacetabular Osteotomies of Pemberton and Dega
Tim Schrader and J. Anthony Gonzales, Jr. 1523

72 Labral Support (Shelf) Procedure for Perthes Disease
J. Richard Bowen 1532

73 Triple Innominate Osteotomy
Dennis R. Wenger and Maya E. Pring 1540

74 Chiari Medial Displacement Osteotomy of the Pelvis
Travis H. Matheney and Brian Snyder 1552
75 Bernese Periacetabular Osteotomy
Travis H. Matheney and Michael B. Millis 1559

76 Surgical Dislocation of the Hip
John Frino and Young-Jo Kim 1569

77 Valgus Osteotomy for Developmental
Coxa Vara
Michael B. Millis and Joshua A. Strassberg 1577

78 Valgus Osteotomy for Perthes Disease
Ellen M. Raney 1583

79 Percutaneous In Situ Cannulated Screw
Fixation of the Slipped Capital
Femoral Epiphysis
Richard S. Davidson and Michelle S. Caird 1589

80 Flexion Intertrochanteric Osteotomy for
Severe Slipped Capital Femoral Epiphysis
Young-Jo Kim and John Frino 1595

SECTION IX FOOT AND ANKLE

81 Triple Arthrodesis
Om Prasad Shrestha, David A. Spiegel, and James J. McCarthy 1600

82 Calcaneal Lengthening Osteotomy for the
Treatment of Hindfoot Valgus Deformity
Vincent S. Mosca 1608

83 Open Lengthening of the Achilles Tendon
Anna V. Cuomo, Norman Y. Otsuka, and Richard E. Bowen 1619

84 Split Posterior Tibial Tendon Transfer
David A. Spiegel, Om Prasad Shrestha, and James J. McCarthy 1626

85 Surgical Correction of Juvenile Bunion
B. David Horn 1633

86 Butler Procedure for Overlapping Fifth Toe
B. David Horn 1637

87 Surgical Treatment of Cavus Foot
Richard M. Schwend and Brad Olney 1639

88 Resection of Calcaneonavicular Coalition
David Scher 1650

89 Excision of Talocalcaneal Coalition
David Scher 1655

90 Ponseti Casting
Blaise Nemeth and Kenneth Noonan 1661

91 Posteromedial and Posterolateral Release for the
Treatment of Resistant Clubfoot
Richard S. Davidson 1674

92 Anterior Tibialis Transfer for Residual
Clubfoot Deformity
Karen S. Myung and Kenneth Noonan 1682

PART 5 ONCOLOGY

SECTION I SURGICAL MANAGEMENT

1 Overview of Endoprosthetic Reconstruction
Martin M. Malawer, Robert M. Henshaw, and Kristen Kellar-Graney 1728

4 Expandable Prostheses
Lee Jeys, Adesegun Abudu, and Robert Grimer 1740

5 Surgical Management of Metastatic Bone Disease: General Considerations
Jacob Bickels and Martin M. Malawer 1749

6 Cryosurgical Ablation of Bone Tumors
Jacob Bickels, Isaac Meller, Yehuda Kollender, and Martin M. Malawer 1757

SECTION II SHOULDER GIRDLE AND
UPPER EXTREMITIES

7 Overview of Resections Around the
Shoulder Girdle
James C. Wittig, Martin M. Malawer, and Kristen Kellar-Graney 1766

8 Total Scapular Resections With
Endoprosthetic Reconstruction
Martin M. Malawer, Kristen Kellar-Graney, and James C. Wittig 1776

9 Proximal Humeral Resection With
Allograft Prosthetic Composite
Steven Gitelis, Gregory P. Nicholson, Walter W. Virkus, Martin M. Malawer, and Benjamin J. Miller 1786

10 Proximal Humerus Resection With
Endoprosthetic Replacement: Intra-articular
and Extra-articular Resections
Martin M. Malawer, James C. Wittig, and Kristen Kellar-Graney 1793

11 Distal Humeral Resection With
Prosthetic Reconstruction
James C. Wittig and Martin M. Malawer 1807

12 Surgical Management of Metastatic
Bone Disease: Humeral Lesions
Jacob Bickels and Martin M. Malawer 1816

13 Axillary Space Exploration and Resections
James C. Wittig, Martin M. Malawer, Kristen Kellar-Graney, and Robert M. Henshaw 1825

14 Forequarter Amputation
Jacob Bickels and Martin M. Malawer 1833

15 Above-Elbow and Below-Elbow Amputations
Jacob Bickels, Yehuda Kollender, and Martin M. Malawer 1842

SECTION III SPINE AND PELVIS

16 Primary and Metastatic Tumors of the Spine:
Total En Bloc Spondylectomy
Katsuro Tomita, Norio Kawahara, and Hideki Murakami 1846

17 Overview on Pelvic Resections:
Surgical Considerations and Classifications
Ernest U. Conrad III, Jason Weisstein, Jennifer Lisle, Amir Sternheim, and Martin M. Malawer 1855

18 Surgical Technique for Resection and
Reconstruction of Supra-acetabular
Metastatic Lesions
Martin M. Malawer and Amir Sternheim 1873
CONTENTS

19 Buttockectomy
James C. Wittig and Martin M. Malawer 1876

20 Surgical Management of Metastatic Bone Disease: Pelvic Lesions
Jacob Bickels and Martin M. Malawer 1879

21 Posterior Flap Hemipelvectomy
Martin M. Malawer and James C. Wittig 1891

22 Anterior Flap Hemipelvectomy
Martin M. Malawer and James C. Wittig 1902

23 Hip Disarticulation
Daria Brooks Terrell 1911

SECTION IV LOWER EXTREMITIES

24 Proximal and Total Femur Resection With Endoprosthetic Reconstruction
Jacob Bickels and Martin M. Malawer 1917

25 Distal Femoral Resections With Endoprosthetic Replacement
Jeffrey J. Eckardt, Martin M. Malawer, Jacob Bickels, and Piya Kiatsevi 1929

26 Proximal Tibia Resection With Endoprosthetic Reconstruction
Jacob Bickels and Martin M. Malawer 1953

27 Fibular Resections
Jacob Bickels and Martin M. Malawer 1964

28 The Use of Free Vascularized Fibular Grafts for Reconstruction of Segmental Bone Defects
Eyal Gur, Yehuda Kollender, Isaac Meller, Aharon Amir, Arik Zaretski, and Jacob Bickels 1974

29 Use of Allografts and Segmental Prostheses for Reconstruction of Segmental Bone Defects
Walter W. Virkus, Robert M. Henshaw, Benjamin J. Miller, and Steven Gitelis 1982

30 Quadriceps Resections
Jacob Bickels, Tamir Pritsch, and Martin M. Malawer 1991

31 Adductor Muscle Group (Medial Thigh) Resection
Jacob Bickels, Martin M. Malawer, and Yehuda Wolf 2000

32 Hamstrings Muscle Group (Posterior Thigh) Resection
Jacob Bickels and Martin M. Malawer 2005

33 Overview of Surgical Resection of Space Sarcomas
Amir Sternheim, Tamir Pritsch, and Martin M. Malawer 2011

34 Popliteal Resections
Jacob Bickels and Tamir Pritsch 2018

35 Soleus Resection
Tamir Pritsch, Amir Sternheim, Jacob Bickels, and Martin M. Malawer 2023

36 Surgical Approach and Management of Tumors of the Sartorial Canal
Martin M. Malawer and Amir Sternheim 2028

37 Surgical Management of Metastatic Bone Disease: Femoral Lesions
Jacob Bickels and Martin M. Malawer 2034

38 Foot and Ankle Amputations: Ray Resections
Loretta B. Chou, H. Thomas Temple, Yvette Ho, and Martin M. Malawer 2047

39 Creating an Above-Knee Amputation Stump After Hip Disarticulation
Amir Sternheim, Daria Brooks Terrell, and Martin M. Malawer 2053

40 Above-Knee Amputation
Daria Brooks Terrell 2060

41 Below-Knee Amputation
Daria Brooks Terrell 2067

42 Foot and Ankle Amputations: Lisfranc/Chopart
Loretta B. Chou, H. Thomas Temple, Yvette Ho, and Martin M. Malawer 2072

PEDiatrics Exam Table 1

Volume Three

PART 6 HAND, WRIST, AND FOREARM

SECTION I ANATOMY, APPROACHES, AND ANESTHESIA

1 Anatomy and Surgical Approaches of the Forearm, Wrist, and Hand
Asif M. Ilyas, Neal C. Chen, and Chaitanya S. Mudgal 2093

2 Anesthetic Considerations for Surgery of the Upper Extremity
John A. Dilger and Hugh M. Smith 2102

3 Arthroscopy of the Hand and Wrist
David J. Slutsky 2114

SECTION II RADIUS AND ULNA FRACTURES AND DISLOCATIONS

4 Open Reduction and Internal Fixation of Diaphyseal Forearm Fractures
Michael R. Boland 2127

5 Reduction and Stabilization of the Distal Radioulnar Joint Following Galeazzi Fractures
Michael R. Boland 2139

6 Corrective Osteotomy for Radius and Ulna Diaphyseal Malunions
Vimala Ramachandran and Thomas F. Varecka 2149

7 Operative Treatment of Radius and Ulna Diaphyseal Nonunions
Rena L. Stewart 2156

8 K-Wire Fixation of Distal Radius Fractures With and Without External Fixation
Christopher Doumas and David J. Bozentka 2162

9 Arthroscopic Reduction and Fixation of Distal Radius and Ulnar Styloid Fractures
William B. Geissler 2172

10 Fragment-Specific Fixation of Distal Radius Fractures
Robert J. Medoff 2183

11 Intramedullary and Dorsal Plate Fixation of Distal Radius Fractures
Pedro K. Beredjiklian and Christopher Doumas 2198
12 Volar Plating of Distal Radius Fractures
John J. Fernandez 2206

13 Bridge Plating of Distal Radius Fractures
Paul A. Martineau, Kevin J. Malone, and Douglas P. Hanel 2218

14 Open Reduction and Internal Fixation of Ulnar Styloid, Head, and Metadiaphyseal Fractures
Tommy Lindau and Andrew J. Logan 2224

15 Corrective Osteotomy for Distal Radius Malunion
David Ring, Diego Fernandez, and Jesse B. Jupiter 2234

SECTION III CARPAL FRACTURES AND AVASCULAR NECROSIS

16 Percutaneous Fixation of Acute Scaphoid Fractures
Peter J. L. Jebson, Jane S. Tan, and Andrew Wong 2244

17 Open Reduction and Internal Fixation of Scaphoid Fractures
Asheesh Bedi and Peter J. L. Jebson 2251

18 Percutaneous Treatment of Grade I to III Scaphoid Nonunions
Joseph F. Slade III† and Greg Merrell 2259

19 Volar Wedge Bone Grafting and Internal Fixation of Scaphoid Nonunions
Evan D. Collins 2266

20 Vascularized Bone Grafting of Avascular Scaphoid Nonunions
Alexander D. Mih 2273

21 Partial Scaphoid Excision of Scaphoid Nonunions
Joseph E. Imbriglia and Justin M. Sacks 2277

22 Surgical Treatment of Carpal Bone Fractures, Excluding the Scaphoid
Kenneth R. Means, Jr. and Thomas J. Graham 2284

23 Osteotomy of the Radius for Treatment of Kienböck Disease
Jeffrey E. Budoff 2295

24 Vascularized Bone Grafting and Capitate Shortening Osteotomy for Treatment of Kienböck Disease
Nilesh M. Chaudhari, Mohamed Khalid, and Thomas R. Hunt III 2305

SECTION IV HAND FRACTURES AND DISLOCATIONS

25 Ligament Stabilization of the Unstable Thumb Carpometacarpal Joint
Richard Y. Kim and Robert J. Strauch 2313

26 Operative Treatment of Thumb Carpometacarpal Joint Fractures
John T. Capo and Colin Harris 2320

27 Dislocations and Chronic Volar Instability of the Thumb Metacarpophalangeal Joint
Robert R. Slater, Jr. 2331

28 Arthroscopic and Open Primary Repair of Acute Thumb Metacarpophalangeal Joint Radial and Ulnar Collateral Ligament Disruptions
Alejandro Badia and Prakash Khanchandani 2342

29 Reconstruction of Chronic Radial and Ulnar Instability of the Thumb Metacarpophalangeal Joint
Steven Z. Glickel and Louis W. Catalano III 2349

30 Operative Treatment of Finger Carpometacarpal Joint Fracture-Dislocations
John J. Walsh IV 2358

31 Operative Treatment of Metacarpal Fractures
Christopher L. Forthman and Thomas J. Graham 2365

32 Operative Treatment of Extra-articular Phalangeal Fractures
Timothy W. Harman, Thomas J. Graham, and Richard L. Uhl 2378

33 Open Reduction and Internal Fixation of Phalangeal Condylar Fractures
Greg Merrell, Kerry Bemers, and Arnold-Peter Weiss 2392

34 Dorsal Block Pinning of Proximal Interphalangeal Joint Fracture-Dislocations
Mark Goleski and Jeffrey Lawton 2404

35 Dynamic External Fixation of Proximal Interphalangeal Joint Fracture-Dislocations
Grey Giddins 2410

36 Open Reduction and Internal Fixation of Proximal Interphalangeal Joint Fracture-Dislocations
Brian Najarian and Jeffrey Lawton 2420

37 Volar Plate Arthroplasty
Albert Leung and Philip E. Blazar 2431

38 Hemi-Hamate Autograft Reconstruction of Unstable Dorsal Proximal Interphalangeal Joint Fracture-Dislocations
Thomas R. Kiehhaber, Rafael M. M. Williams, and Soma I. Lilly 2436

39 Operative Treatment of Distal Interphalangeal Joint Fracture-Dislocations
Leo T. Kroonen and Eric P. Hofmeister 2445

40 Corrective Osteotomy for Metacarpal and Phalangeal Malunion
Mohamed Khalid, Nilesh M. Chaudhari, and Thomas R. Hunt III 2452

SECTION V WRIST INSTABILITIES

41 Arthroscopic Evaluation and Treatment of Scapholunate and Lunotriquetral Ligament Disruptions
Alexander H. Payatakes, Alex M. Meyers, and Dean G. Sotereanos 2459

42 Open Scapholunate Ligament Repair and Augmentation
Alex M. Meyers, Alexander H. Payatakes, and Dean G. Sotereanos 2467

43 Capsulodesis for Treatment of Scapholunate Instability
Angel Ferreres, Marc García-Elías, and Andrew Chin 2472

44 Tenodesis for Treatment of Scapholunate Instability
Marc García-Elías and Angel Ferreres 2480

45 Bone–Ligament–Bone Reconstruction of the Scapholunate Ligament
Anthony M. DeLuise, Jr. and Randall W. Culp 2488

† deceased

PART 8 FOOT AND ANKLE

SECTION I FOREFOOT

1 Distal Chevron Osteotomy: Perspective 1
   Hans-Joerg Trnka and Stefan G. Hofstetter 3481

2 Distal Chevron Osteotomy: Perspective 2
   Paul Hamilton, Sam Singh, and Michael G. Wilson 3488

3 Biplanar Distal Chevron Osteotomy
   Caio Nery 3491
CONTENTS

27 Bone-Block Distraction of the First Metatarsophalangeal Joint
Hans-Joerg Trnka and Stefan G. Hofstaetter  3656

28 Surgical Management of Turf Toe Injuries
Christopher W. Nicholson and Robert B. Anderson  3665

29 Internal Fixation of Sesamoid Fractures
Geert I. Pagenstert, Victor Valderrabano, and Beat Hintermann  3674

30 Tibial Sesamoidectomy
Simon Lee, Johnny Lin, and George B. Holmes, Jr.  3681

31 Flexor-to-Extensor Tendon Transfer for Flexible Hammer Toe Deformity
Emilio Wagner  3688

32 Hammer Toe Correction
Lloyd C. Briggs, Jr.  3696

33 Weil Lesser Metatarsal Shortening Osteotomy
Stefan G. Hofstaetter and Hans-Joerg Trnka  3707

34 Angular Deformity of the Lesser Toes
Adolph S. Flemister, Jr., and Brian D. Giordano  3714

35 Surgical Correction of Bunionette Deformity
Johnny T. C. Lau, W. Bryce Henderson, and Gilbert Yee  3730

36 Rheumatoid Forefoot Reconstruction
Thomas G. Padanilam  3736

37 Morton’s Neuraoma and Revision Morton’s Neuraoma Excision
David R. Richardson  3743

38 Uniportal Endoscopic Decompression of the Interdigital Nerve for Morton’s Neuraoma
Steven L. Shapiro  3751

SECTION II MIDFOOT

39 Plantarflexion Opening Wedge Medial Cuneiform Osteotomy
Jeffrey E. Johnson  3755

40 Tarsometatarsal Arthrodesis
Ian L. D. Le and Mark E. Easley  3761

41 Midfoot Arthrodesis
Mark E. Easley  3766

42 Percutaneous Midfoot Osteotomy With External Fixation
Bradley M. Lamm, Ahmed Thabet, John E. Herzenberg, and Dror Paley  3788

43 Surgical Stabilization of Nonplantigrade Charcot Arthropathy of the Midfoot
Michael S. Pinzur  3794

44 Axial Screw Technique for Midfoot Arthrodesis in Charcot Foot Deformities
Vincent James Sammarco and G. James Sammarco  3802

45 Minimally Invasive Realignment Surgery of the Charcot Foot
Bradley M. Lamm and Dror Paley  3809

SECTION III HINDFOOT

46 Flexor Digitorum Longus Transfer and Medial Displacement Calcaneal Osteotomy
Gregory P. Guyton  3814

47 Lateral Column Lengthening
Donald R. Bohay and John G. Anderson  3823

48 Spring Ligament Reconstruction
Jonathan T. Deland  3832

49 Calcaneonavicular Coalition Resection in the Adult Patient
Aaron T. Scott and H. Robert Tenner  3839

50 Isolated Subtalar Arthrodesis
Aaron T. Scott and Robert S. Adelaar  3843

51 Surgical Management of Calcaneal Malunions
Michael P. Clare and Roy W. Sanders  3849

52 Calcaneal Osteotomy and Subtalar Arthrodesis for Calcaneal Malunions
Michael M. Romash  3859

53 Traditional Triple Arthrodesis
Mark E. Easley  3868

54 Single-Incision Medial Approach for Triple Arthrodesis
Clifford L. Jeng  3879

55 Comprehensive Correction of Cavovarus Foot Deformity
Michael Barnett, Arthus Manoli, Bruce J. Sangeorzan, Gregory C. Pomeroy, and Brian C. Toolan  3885

56 Management of Equinocavovarus Foot Deformity
Wolfram Wenz and Thomas Dreher  3891

57 Plantar Fascia Release in Combination With Proximal and Distal Tarsal Tunnel Release
John S. Gould and Benedict F. DiGiovanni  3911

58 Endoscopic Plantar Fasciotomy
Steven L. Shapiro  3920

59 Transection and Burial of Neuromas of the Foot and Ankle
Stuart D. Miller, Blake L. Ohlson, and Michael Scherb  3925

60 Barrier Procedures for Adhesive Neuralgia
Stuart D. Miller and Venus R. Rivera  3933

SECTION IV ANKLE

61 Distraction Arthroplasty for Ankle Arthritis
Richard E. Gelman and Douglas N. Beaman  3941

62 Supramalleolar Osteotomy With Internal Fixation: Perspective 1
Emmanouil D. Stamatis  3953

63 Supramalleolar Osteotomy With Internal Fixation: Perspective 2
Emmanouil D. Stamatis  3953

64 Supramalleolar Osteotomy With Internal Fixation: Perspective 3
Emmanouil D. Stamatis  3953

65 Supramalleolar Osteotomy With External Fixation: Perspective 1
Austin T. Fragomen and S. Robert Rozbruch  3976

66 Supramalleolar Osteotomy With External Fixation: Perspective 2
Bradley M. Lamm, Shiy John, John E. Herzenberg, and Dror Paley  3995

67 Total Ankle Shell Allograft Reconstruction
Michael E. Brage and Keri A. Reese  4000

68 The STAR (Scandinavian Total Ankle Replacement) Total Ankle Arthroplasty
Mark E. Easley, James A. Nunley II, and James K. DeOrio  4007
69 The HINTEGRA Total Ankle Arthroplasty
Beat Hintermann and Alexej Barg 4022

70 The BOX Total Ankle Arthroplasty
Sandro Giannini, Matteo Romagnoli, Deianira Luciani, Fabio Catani, and Alberto Leardini 4032

71 The Salto and Salto-Talaris Total Ankle Arthroplasty
Michel Bonnin, Brian Donley, Thierry Judet, and Jean-Alain Colombier 4042

72 Mobility Total Ankle Arthroplasty
Pascal F. Rippstein, Mark E. Easley, and J. Chris Coetzee 4056

73 INBONE Total Ankle Arthroplasty
James K. DeOrio, Mark E. Easley, James A. Nunley II, and Mark A. Reiley 4072

74 TNK Total Ankle Arthroplasty
Yasuhito Tanaka and Yoshinori Takakura 4085

75 The Agility Total Ankle Arthroplasty
J. Chris Coetzee and Steven L. Haddad 4093

76 Revision Agility Total Ankle Arthroplasty
Steven L. Haddad 4102

77 Ankle Arthrodesis
Mark E. Easley 4123

78 Transfibular Approach for Ankle Arthrodesis
Alex J. Kline and Dane K. Wukich 4140

79 The Miniarthrotomy Technique for Ankle Arthrodesis
Emmanouil D. Stamatis 4146

80 Arthroscopic Ankle Arthrodesis
James P. Tasto 4154

81 Tibiotalocalcaneal Arthrodesis Using a Medullary Nail
George E. Quill, Jr., and Stuart D. Miller 4161

82 Tibiotalocalcaneal Arthrodesis Using Lateral Blade Plate Fixation
Christopher P. Chiodo and Catherine E. Johnson 4173

83 Tibiocalcaneal Arthrodesis Using Blade Plate Fixation
Richard Alvarez, Delan Gaines, and Mark E. Easley 4179

84 Treatment of Bone Loss, Avascular Necrosis, and Infection of the Talus With Circular Tensioned Wire Fixators
James J. Hutson, Jr., Robert Rochman, and Oladapo Alade 4192

85 Femoral Head Allograft for Large Talar Defects
Bryan D. Den Hartog 4203

86 Posterior Blade Plate for Salvage of Failed Total Ankle Arthroplasty
Mark Ritter, Florian Nickisch, and Christopher W. DiGiovanni 4208

SECTION V SPORTS-RELATED PROCEDURES FOR ANKLE AND HINDFOOT

87 Arthroscopy of the Ankle
Jorge I. Acevedo and Peter Mangone 4216

88 Microfracture for Osteochondral Lesions of the Talus
Hajo Thermann and Christoph Becher 4222

89 Posterior Ankle Impingement Syndrome
Javier Maquirriain 4229

90 Posterior Ankle Arthroscopy and Hindfoot Endoscopy
C. Niek van Dijk and Tahir Öğüt 4234

91 Endoscopic Treatment of Posterior Ankle Impingement Through a Posterior Approach
Phinit Phisitkul and Annunziato Amendola 4243

92 Subtalar Arthroscopy
Carol Frey 4251

93 Osteochondral Transfer for Osteochondral Lesions of the Talus
Mark E. Easley and Justin Orr 4259

94 Anterior Tibial Osteotomy for Osteochondral Lesions of the Talus
G. James Sammarco 4271

95 Osteochondral Lesions of the Talus: Structural Allograft
Mark E. Easley, Samuel B. Adams, Jr., and James A. Nunley II 4274

96 Autologous Chondrocyte Transplantation
Markus Walther 4288

97 Chevron-Type Medial Malleolar Osteotomy
Bruce Cohen 4298

98 Modified Brostrom and Brostrom-Evans Procedures
Paul J. Hecht, Justin S. Cummins, Mark E. Easley, and Dean C. Taylor 4301

99 Anatomic Repair of Lateral Ankle Instability
Gregory C. Berlet, Geoffrey S. Landis, Christopher F. Hyer, and Terrence M. Philbin 4314

100 Hamstring Autografting/Augmentation for Lateral Ankle Instability
Alastair Younger and Heather Barske 4322

101 Lateral Ankle Ligament Reconstruction Using Allograft and Interference Screw Fixation
William C. McGarvey and Thomas O. Clanton 4331

102 Chronic Lateral Ankle Instability
Markus Walther 4340

103 Deltoid Ligament Reconstruction
Eric M. Bluman and Richard J. deAsla 4347

104 Medial Ankle/Deltoid Ligament Reconstruction
Beat Hintermann and Victor Valderrabano 4354

105 Open Achilles Tendon Repair
Sameh A. Labib 4367

106 Limited Open Repair of Achilles Tendon Ruptures: Perspective 1
Mathieu Assal 4374

107 Mini-Open Achilles Tendon Repair: Perspective 2
Mark E. Easley, Marc Merian-Genast, and Mathieu Assal 4380

108 Percutaneous Achilles Tendon Repair: Perspective 1
Karen M. Sutton, Sandra L. Tomak, and Lamar L. Fleming 4387

109 Percutaneous Achilles Tendon Repair: Perspective 2
Nicholas A. Ferran, Ansar Mahmood, and Nicola Maffulli 4393

110 Chronic Achilles Tendon Ruptures Using V-Y Advancement and FHL Transfer
Steven M. Raikin 4398
111 Chronic Achilles Tendon Ruptures Using Hamstring/Peroneal Tendons
Nicholas A. Ferran and Nicola Maffulli 4406

112 Chronic Achilles Tendon Ruptures Using Allograft Reconstruction
Andrew P. Molloy and Mark S. Myerson 4412

113 Soft Tissue Expansion in Revision/Complex Achilles Tendon Reconstruction
Jorge I. Acevedo 4417

114 Retrocalcaneal Bursoscopy
Angus M. McBryde and Fred W. Ortmann 4419

115 Insertional Achilles Tendinopathy
Mark E. Easley and Matthew J. DeOrio 4423

116 Surgical Management of Calcific Insertional Achilles Tendinopathy Using a Lateral Approach
Anthony Watson 4433

117 Flexor Hallucis Longus Tendon Augmentation for the Treatment of Insertional Achilles Tendinosis
William C. McGarvey and Thomas O. Clanton 4437

118 Open Management of Achilles Tendinopathy
Nicola Maffulli and Umile Giuseppe Longo 4443

119 Flexor Hallucis Longus Transfer for Achilles Tendinosis
Bryan D. Den Hartog 4447

120 Proximal Mini-Invasive Grafting of Plantaris Tendon
Geert I. Pagenstert and Beat Hintzmann 4454

121 Repair of Peroneal Tendon Tears
Brad Dresher and Brian Donley 4458

122 Reconstruction of Chronic Peroneal Tendon Tears
Keith L. Wapner, Selene G. Parekh, and Wen Chao 4462

123 Repair of Dislocating Peroneal Tendons: Perspective 1
Sheldon Lin, Karl Bergmann, Vikrant Azad, Virak Tan, Enyi Okereke, and Siddhant Mehta 4468

124 Repair of Dislocating Peroneal Tendons: Perspective 2
Florian Nickisch, Scott B. Shawen, and Robert B. Anderson 4477

125 Reconstruction of Tibialis Anterior Tendon Ruptures
James Santangelo and Mark E. Easley 4484

126 Tendon Transfer for Foot Drop
Mark E. Easley and Aaron T. Scott 4488

PART 9 SPINE

SECTION I APPROACH TO THE SPINE

1 Anterior Cervical Approaches
John Heflin and John M. Rhee 4507

2 Posterior Cervical Approach
Raj Rao and Satyajit V. Marawar 4516

3 Anterior Thoracic Approach
Morgan N. Chen, Sheeraz A. Qureshi, and Andrew C. Hecht 4523

4 Anterior Lumbar Approach
P. Justin Tortolani, Samer Sadey, and Ira L. Fedder 4530

5 Posterior Thoracic and Lumbar Approaches
Thomas Stanley, Michael J. Lee, Mark Dumonski, and Kern Singh 4537

SECTION II CERVICAL SPINE SURGERY

6 Anterior Cervical Discectomy and Fusion With and Without Instrumentation
John M. Rhee, Claude Jarrett, and Sam W. Wiesel 4543

7 Anterior Cervical Corpectomy and Fusion With Instrumentation
Claude Jarrett and John M. Rhee 4554

8 Posterior Cervical Foraminotomy
Jacob M. Buchowski, Ronald A. Lehman, Jr., and K. Daniel Riew 4562

9 Cervical Laminoplasty: Open and French Door
S. Tim Yoon and James S. Kercher 4568

10 Posterior Cervical Fusion With Instrumentation
Raj Rao and Satyajit V. Marawar 4576

11 Occipitocervical and C1–2 Fusion and Instrumentation
Youjeong Kim, Maneesh Bawa, and John G. Heller 4586

SECTION III THORACOLUMBAR SPINE SURGERY

12 Lumbar Discectomy
Bradley K. Weiner and Aristidis Zibis 4595

13 Lumbar Decompression
Bradley K. Weiner and Aristidis Zibis 4603

14 Posterolateral Thoracolumbar Fusion With Instrumentation
Mark Dumonski, Thomas Stanley, Michael J. Lee, Bart Wojewnik, and Kern Singh 4609

15 Transforaminal and Posterior Lumbar Interbody Fusion
Mitchell F. Reiter and Saad B. Chaudhary 4616

16 Anterior Thoracic Corpectomy
Sheeraz A. Qureshi, Morgan N. Chen, and Andrew C. Hecht 4628

17 Anterior Lumbar Interbody Fusion, Disc Replacement, and Corpectomy
P. Justin Tortolani, Paul C. McAfee, and Matthew N. Scott-Young 4634

18 Adult Scoliosis
Andrew P. White, James S. Harrop, and Todd J. Albert 4646

19 Iliac Crest Bone Graft Harvesting
Michael J. Lee, Thomas Stanley, Mark Dumonski, Patrick Cahill, Daniel Park, and Kern Singh 4659

FOOT AND ANKLE EXAM TABLE 1

SPINE EXAM TABLE 1

INDEX I-1
PART 1 SPORTS MEDICINE

Christopher R. Adams, MD
Orthopaedic Surgeon
Advanced Shoulder Orthopaedics
Jupiter, Florida

Julie E. Adams, MD
Assistant Professor of Orthopaedic Surgery
University of Minnesota
Minneapolis, Minnesota

Christina R. Allen, MD
Associate Clinical Professor of Orthopaedic Surgery
University of California
San Francisco, California

Michael J. Angel, MD
Orthopaedic Sports Medicine Fellow
Kerlan Jobe Orthopaedic Clinic
Los Angeles, California

Robert A. Arciero, MD
Professor of Orthopaedics
University of Connecticut Health Center
John Dempsey Hospital
Farmington, Connecticut

Steve Aviles, MD
Department of Orthopaedic Surgery
Iowa Orthopaedic Center
Moline, Iowa

Frederick M. Azar, MD
Professor of Orthopaedic Surgery
University of Tennessee
Residency Program Director
Sports Medicine Fellowship Director
Campbell Clinic
Memphis, Tennessee

F. Alan Barber, MD
Fellowship Director
Plano Orthopedic Sports Medicine and Spine Center
Plano, Texas

Mark J. Billante, MD
Physician
Greater Austin Orthopaedics
Austin, Texas

Matthew T. Boes, MD
Raleigh Orthopaedic Clinic
Raleigh, North Carolina

Kevin F. Bonner, MD
Assistant Professor
Eastern Virginia Medical School
Jordan-Young Institute
Sentara Leigh Hospital
Virginia Beach, Virginia

Jesse C. Botker, MD
Orthopaedic Surgery Chief Resident
University of Minnesota
Minneapolis, Minnesota

Craig R. Bottini, MD
Chief of Surgery
Assistant Chief Medical Officer
Aspetar Orthopaedic & Sports Medicine Hospital
Doha, Qatar

James P. Bradley, MD
Clinical Professor of Orthopaedic Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Anthony M. Buoncristiani, MD
Orthopaedic Surgeon
St. Luke’s Wood River Medical Center
Ketchum, Idaho

Stephen S. Burkhardt, MD
Director of Orthopaedic Education
The San Antonio Orthopaedic Group
The Orthopaedic Institute
San Antonio, Texas

Charles Bush-Joseph, MD, BA
Professor of Orthopaedic Surgery
Rush University Medical Center
Chicago, Illinois

J. W. Thomas Byrd, MD
Nashville Sports Medicine Foundation
Nashville, Tennessee

Eric W. Carson, MD
Associate Professor
Division of Sports Medicine
Department of Orthopaedic Surgery
University of Virginia
Charlottesville, Virginia

Mark S. Cohen, MD
Professor
Director, Hand and Elbow Section
Department of Orthopaedic Surgery
Rush University Medical Center
Chicago, Illinois

Steven B. Cohen, MD
Assistant Professor of Orthopaedic Surgery
Thomas Jefferson University
Rothman Institute Orthopaedics
Philadelphia, Pennsylvania

Brian Cole, MD, MBA
Professor
Section of Sports Medicine
Departments of Orthopaedic Surgery and Anatomy & Cell Biology
Section Head, Cartilage Restoration Center at Rush
Rush University Medical Center
Chicago, Illinois

Anne E. Colton, MD
Premier Orthopaedics
Broomall, Pennsylvania

John E. Conway, MD
Private Practice
Texas Health Harris Methodist Fort Worth Hospital
Fort Worth, Texas

David A. Coons, DO
Multicare Orthopedics and Sports Medicine
Tacoma, Washington

Andrew J. Cosgrove, MD
Professor, Orthopaedic Surgery
Director, Sports Medicine and Shoulder Surgery
Department of Orthopaedic Surgery
Johns Hopkins University
Lutherville, Maryland

Thomas M. DeBerardino, MD
Associate Professor of Orthopaedic Surgery
University of Connecticut Health Center
Farmington, Connecticut

David R. Diduch, MS, MD
Professor of Orthopaedic Surgery
Head Orthopaedic Team Physician
University of Virginia
Charlottesville, Virginia

Ivica Ducic, MD, PhD
Associate Professor
Chief, Peripheral Nerve Surgery
Department of Plastic Surgery
Georgetown University Hospital
Washington, District of Columbia

Jeffrey S. Earhart, MD
Resident
Department of Orthopaedic Surgery
Fenberg School of Medicine
Northwestern University
Chicago, Illinois

Gregory C. Fanelli, MD
Orthopaedic Surgery
Geisinger Sports Medicine
Danville, Pennsylvania

David L. Feingold, MD
Chief, Department of Orthopaedics
Olive View Medical Center
West Hills, California

Larry D. Field, MD
Clinical Instructor
Department of Orthopaedic Surgery
University of Mississippi School of Medicine
Director, Upper Extremity Service
Mississippi Sports Medicine and Orthopaedic Center
Jackson, Mississippi

Donald C. Fithian, MD
Director, San Diego Knee and Sports Medicine Fellowship
Kaiser Permanente, San Diego
El Cajon, California
Matthew T. Provencher, MD
Associate Professor of Surgery
Director, Orthopaedic Shoulder and Sports Surgery
Department of Orthopaedic Surgery
Naval Medical Center San Diego
San Diego, California

R. David Rabalais, MD
Clinical Assistant Professor of Medicine
Department of Orthopaedic Surgery
Louisiana State University Health Science Center
New Orleans, Louisiana

William G. Rodkey, DVM, Diplomate ACVS
Chief Scientific Officer
Steadman Hawkins Research Foundation
Vail, Colorado

Anthony A. Romeo, MD
Department of Orthopaedic Surgery
Rush University Medical Center
Chicago, Illinois

J. R. Rudzki, MD
Clinical Assistant Professor
Department of Orthopaedic Surgery
George Washington University School of Medicine
Washington, District of Columbia

John-Paul Rue, MD, CDR, MC, USN
Assistant Professor
Department of Surgery
Uniformed Services University of Health Sciences
Director of Sports Medicine
National Naval Medical Center
Bethesda, Maryland

Marc Safran, MD
Professor of Orthopaedic Surgery
Stanford University
Stanford, California

Felix H. Savoie, III, MD
Lee C. Schlesinger Professor of Clinical Orthopaedics
Tulane University School of Medicine
New Orleans, Louisiana

John A. Scanelli III, MD
Resident
Department of Orthopaedic Surgery
University of Virginia
Charlottesville, Virginia

Robert C. Schenck, MD
Professor and Chairman
Department of Orthopaedics and Rehabilitation
University of New Mexico
Albuquerque, New Mexico

Jon K. Sekiya, MD
Associate Professor
MedSport—Department of Orthopaedic Surgery
University of Michigan
Ann Arbor, Michigan

Nicholas A. Sgaglione, MD
Associate Clinical Professor of Orthopaedic Surgery
North Shore Long Island Jewish Health System
Great Neck, New York

Benjamin S. Shaffer, MD
Washington Orthopaedics & Sports Medicine
Chevy Chase, Maryland

Ryan W. Simovitch, MD
Palm Beach Orthopaedic Institute
Palm Beach Gardens, Florida

Jeffrey T. Spang, MD
Assistant Professor of Orthopaedics
University of North Carolina
Chapel Hill, North Carolina

Matthew A. Stanich, MD
Resident
University of California, San Francisco
San Francisco, California

Erick S. Stark, MD
Tri-City Orthopedics
Oceanside, California

J. Richard Steadman, MD
Orthopaedic Surgeon and Principal Steadman Hawkins Clinic
Vail, Colorado

Scott P. Steinmann, MD
Professor of Orthopedic Surgery
Mayo Clinic College of Medicine
Rochester, Minnesota

Rebecca M. Stone, MS, ATC
Minnesota Sports Medicine
Twin Cities Orthopedics
Eden Prairie, Minnesota

Robert T. Sullivan, BS, MD
Orthopedic Surgeon/Sports Medicine
United States Air Force Academy
USAF Academy, Colorado

Kenneth G. Swan, Jr., MD
Department of Orthopaedic Surgery
Robert Wood Johnson University Hospital
New Brunswick, New Jersey

Robert Z. Tashjian, MD
Department of Orthopaedics
University of Utah Orthopaedic Center
Salt Lake City, Utah

Richard J. Thomas, MD
OrthoGeorgia Orthopaedic Specialists
Macon, Georgia

Fotios P. Tjoumakaris, MD
Assistant Professor of Orthopaedic Surgery
University of Pennsylvania School of Medicine/Penn Sports Medicine
Philadelphia, Pennsylvania

Michael S. Todd, MC
Orthopaedic Surgery Service
William Beaumont Army Medical Center
El Paso, Texas

Daniel J. Tomaszewski, MD
Department of Orthopaedic Surgery
Geisinger Clinic
Danville, Pennsylvania

Bradley B. Veazey, MD
Assistant Professor
Department of Orthopaedic Surgery and Rehabilitation
Texas Tech University
Lubbock, Texas

Christian J. H. Veillette, MD, MSc, FRCS
Assistant Professor
Division of Orthopaedic Surgery
University of Toronto
Toronto Western Hospital
University Health Network
Toronto, Ontario, Canada

Andrew J. Veitch, MD
Assistant Professor
Department of Orthopaedics and Rehabilitation
University of New Mexico
Albuquerque, New Mexico

Winston J. Warne, MD
Associate Professor of Orthopaedics and Sports Medicine
Chief of Shoulder and Elbow Surgery
University of Washington
Seattle, Washington

Jon J. P. Warner, MD
Professor of Orthopaedic Surgery
Chief of Harvard Shoulder Service
Partner’s Health Care System
Massachusetts General Hospital
Brigham and Women’s Hospital
Boston, Massachusetts

Daniel C. Wascher, MD
Professor
Department of Orthopaedics and Rehabilitation
University of New Mexico
Albuquerque, New Mexico

Carl H. Wierks, MD
Orthopaedic Chief Resident
Johns Hopkins Hospital
Baltimore, Maryland

Jocelyn R. Wittstein, MD
Resident
Department of Orthopaedic Surgery
Duke University Medical Center
Durham, North Carolina

Ken Yamaguchi, MD
Professor of Orthopaedic Surgery
Sam and Marilyn Fox Distinguished Professor of Orthopaedic Surgery
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Jeff Anglen, MD, FACS
Professor and Chairman of Orthopaedics
Indiana University School of Medicine
Indianapolis, Indiana

PART 2 PELVIS AND LOWER EXTREMITY TRAUMA

Animesh Agarwal, MD
Associate Professor of Orthopaedics
Chief, Division of Orthopaedic Trauma
University of Texas Health Science Center at San Antonio
San Antonio, Texas

PART 2 PELVIS AND LOWER EXTREMITY TRAUMA
Michael R. Baumgaertner, MD
Professor
Chief, Orthopaedic Trauma Service
Department of Orthopaedics
Yale University School of Medicine
New Haven, Connecticut

James B. Carr, MD
Associate Clinical Professor
Department of Orthopedic Surgery
University of South Carolina
Columbia, South Carolina

Michael P. Clare, MD
Director of Fellowship Education
Foot and Ankle Fellowship
Florida Orthopaedic Institute
Tampa, Florida

William R. Creery, MD
Vice Chairman and Associate Professor of Orthopaedic Surgery
Boston University School of Medicine
Boston Medical Center
Boston, Massachusetts

Brett D. Crist, MD
Assistant Professor
Department of Orthopaedic Surgery
University of Missouri
Columbia, Missouri

Nicholas Divaris, MD
Assistant Professor
Department of Orthopaedics
State University of New York at Stony Brook
Stony Brook, New York

Kenneth A. Egol, MD
Associate Professor
Department of Orthopaedic Surgery
NYU Hospital for Joint Diseases
New York, New York

Thomas Ellis, MD
Associate Professor of Orthopaedics
The Ohio State University College of Medicine
Columbus, Ohio

John C. P. Floyd, MD
Department of Orthopaedic Trauma
The Medical Center of Central Georgia
Macon, Georgia

Darin Friess, MD
Assistant Professor of Orthopaedics & Rehabilitation
Oregon Health & Science University
Portland, Oregon

Andrew Furey, MSc, MD, FRCSC
Assistant Professor
Department of Surgery
Memorial University of Newfoundland
St. John’s, Newfoundland, Canada

Michael S. H. Kain, MD
Chief Resident, Orthopaedic Surgery
Boston University Medical Center
Boston, Massachusetts

David E. Karges, DO
Associate Professor
Department of Orthopaedic Surgery
St. Louis University
St. Louis, Missouri

Phyllis Kobbe, MD
Department of Orthopaedic Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Stephen Kottmeier, MD
Associate Professor of Orthopaedics
University Hospital and Medical Center at Stony Brook
Stony Brook, New York

Ronald Lakatos, MD
Assistant Professor of Orthopaedics
The Ohio State University Medical Center
Columbus, Ohio

Mark A. Lee, MD
Associate Professor of Orthopaedic Surgery–Trauma
University of California, San Francisco School of Medicine
San Francisco, California

Seth P. Levitz, MD
Department of Orthopaedic Surgery
NorthShore University Health System
Evaston, Illinois

Brian Mullis, MD
Chief and Assistant Professor, Orthopaedic Trauma Service
Indiana University School of Medicine
Indianapolis, Indiana

Robert O’Toole, MD
Assistant Professor
Department of Orthopaedic Surgery
University of Maryland School of Medicine
Baltimore, Maryland

Matthew E. Oetgen, MD
Clinical Instructor
Department of Orthopaedic Surgery and Sports Medicine
Children’s National Medical Center
Washington, District of Columbia

Hans Christoph Pape, MD
F. Pauwels Professor and Chairman
Department of Orthopaedic Surgery
University of Aachen Medical Center
Aachen, Germany

George Parnal, MD
Department of Orthopaedics
Eastern Maine Medical Center
Bangor, Maine

Laura S. Pfeiffer, MD
Assistant Professor of Orthopaedics
The Ohio State University Medical Center
Columbus, Ohio

Michael Prayson, MD
Associate Professor of Orthopaedic Surgery
Wright State University Boonshoft School of Medicine
Miami Valley Hospital
Dayton, Ohio

William M. Rice, MD
Associate Professor
Department of Orthopaedic Surgery
Washington University School of Medicine
St. Louis, Missouri

Toby M. Risko, MD
Assistant Professor of Orthopaedics
Texas Tech University
Lubbock, Texas

Thomas A. Russell, BS, MD
Professor of Orthopaedic Surgery
Campbell Clinic/University of Tennessee Department of Orthopaedics
Elvis Presley Trauma Center
University of Tennessee
Eads, Tennessee

Henry Claude Sagi, MD
Assistant Clinical Professor
Department of Orthopaedic Surgery and Orthopaedic Trauma Service
University of South Florida
Tampa General Hospital
Tampa, Florida

Roy W. Sanders, MD
Director, Orthopaedic Trauma Service
Florida Orthopaedic Institute
Tampa, Florida

Jodi Siegel, MD
Assistant Professor of Orthopaedics
Department of Orthopaedics and Physical Rehabilitation
University of Massachusetts Medical School
University of Massachusetts Memorial Medical Center
Worcester, Massachusetts

J. Benjamin Smucker, MD
Orthopaedic Resident
Metrohealth Hospital
Cleveland, Ohio

John K. Sontich, MD
Associate Professor of Surgery, Orthopaedics
Metrohealth Medical Center
Cleveland, Ohio

Natalie L. Talbou, MPAS, PA-C
Department of Orthopaedic Surgery
St. Elizabeth Health Center
Youngstown, Ohio

David C. Templeman, MD
Associate Professor of Orthopaedic Surgery
University of Minnesota
Hennepin County Medical Center
Minneapolis, Minnesota

Paul Tornetta III, MD
Professor and Vice Chairman
Department of Orthopaedic Surgery
Boston University Medical Center
Boston, Massachusetts

J. Tracy Watson, MD
Professor of Orthopaedic Surgery
Chief, Division of Orthopaedic Traumatology
St. Louis University School of Medicine
St. Louis, Missouri
PART 3 ADULT RECONSTRUCTION

Anish K. Amin, MBChB, MRCSEd  
Specialist Registrar  
Department of Orthopaedic and Trauma Surgery  
New Royal Infirmary of Edinburgh  
Edinburgh, Scotland

Robert A. Arciero, MD  
Professor and Chief of Sports Medicine  
Department of Orthopaedic Surgery  
University of Connecticut Health Center  
Farmington, Connecticut

Matthew S. Austin, MD  
Assistant Professor of Orthopaedic Surgery  
Thomas Jefferson University Hospital  
Rothman Institute  
Philadelphia, Pennsylvania

B. Sonny Bal, MD, MBA  
Associate Professor  
Department of Orthopaedic Surgery  
University of Missouri  
Columbia, Missouri

Martin Beck, MD, PD, Dr.med.  
Department of Orthopaedic Surgery  
Canton Hospital Lucerne  
Lucerne, Switzerland

Christopher P. Beauchamp, MD  
Associate Professor of Orthopaedics  
Mayo College of Medicine  
Phoenix, Arizona

Benjamin Bender, MD  
Joint Replacement Specialist  
Assuta Hospital  
Tel-Aviv, Israel

Keith R. Berend, MD  
Clinical Assistant Professor  
Department of Orthopaedics  
The Ohio State University  
New Albany, Ohio

Michael E. Berend, MD  
Orthopaedic Surgeon  
Center for Hip & Knee Surgery  
St. Francis Hospital  
Mooresville, Indiana

Hari P. Bezawada, MD  
Assistant Clinical Professor  
Department of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

James Bicos, MD  
Department of Orthopedics and Sports Medicine  
St. Vincent Medical Center  
Carmel, Indiana

Thomas E. Brown, MD  
Associate Professor of Orthopaedic Surgery  
University of Virginia School of Medicine  
Charlottesville, Virginia

Shawn M. Brubaker, DO  
Staff, Shasta Orthopaedics and Sports Center  
Redding, California

Robert H. Cho, MD  
Orthopaedic Resident  
Department of Orthopaedic Surgery  
Drexel University College of Medicine  
Philadelphia, Pennsylvania

Christian P. Christensen, MD  
Head, Adult Reconstruction  
Lexington Clinic  
Assistant Clinical Professor  
University of Kentucky  
Lexington, Kentucky

John C. Clohisy, MD  
Professor of Orthopaedic Surgery  
Washington University Medical School  
St. Louis, Missouri

Janet D. Conway, MD  
Head of Bone and Joint Infection  
Rubin Institute for Advanced Orthopedics  
Sinai Hospital  
Baltimore, Maryland

Marcus Crestani, MD  
Department of Orthopaedics  
Hospital Moinhos de Vento  
Santa Casa, Brazil

Craig J. Della Valle, MD  
Associate Professor of Orthopaedic Surgery  
Rush University Medical Center  
Westchester, Illinois

Jonathan Garino, MD  
Associate Professor  
Department of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

Nelson V. Greidanus, MD, MPH, FRCSC  
Assistant Professor  
Department of Orthopaedics  
University of British Columbia  
Vancouver, British Columbia, Canada

David Gusmao, MD  
Department of Orthopaedics  
Hospital Moinhos de Vento  
Santa Casa, Brazil

Mark A. Hartzband, MD  
Senior Attending Director, Total Joint Replacement Service  
Department of Orthopaedic Surgery  
Hackensack University Medical Center  
Hackensack, New Jersey

Philipp Henle, MD  
Resident  
Department of Orthopaedic Surgery  
Inselspital, Bern University Hospital  
Bern, Switzerland

Matthew S. Hepinstall, MD  
Fellow, Adult Reconstruction & Joint Replacement  
Department of Orthopaedic Surgery  
Hospital for Special Surgery  
New York, New York

William J. Hozacl, MD  
Professor of Orthopedics  
Department of Orthopaedic Surgery  
The Rothman Institute  
Thomas Jefferson University Hospital  
Philadelphia, Pennsylvania

Cale A. Jacobs, PhD  
Director of Development  
End Range of Motion Improvement, Inc.  
Assistant Professor, Adjunct Title Series  
College of Health Sciences  
University of Kentucky  
Suwanee, Georgia

S. Mehdi Jafari, MD  
Assistant Professor  
Department of Orthopaedic Surgery  
Tehran University of Medical Sciences  
Shariati Hospital  
Tehran, Iran

Kang-Il Kim, MD, PhD  
Associate Professor and Chief  
Center for Joint Diseases  
Department of Orthopaedic Surgery  
Kyeong Hee University School of Medicine  
East-West Neo Medical Center  
Seoul, Korea

Winston Y. Kim, MBChB, MSc, FRCS  
Lecturer and Consultant Orthopaedic Surgeon  
The Alexandra Hospital  
University of Manchester  
Cheadle, Cheshire, United Kingdom

Brian A. Klatt, MD  
Assistant Professor  
Department of Orthopaedic Surgery  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania

Gregg R. Klein, MD  
Attending Physician  
Department of Orthopaedic Surgery  
Hackensack University Medical Center  
Hackensack, New Jersey

Gwo-Chin Lee, MD  
Assistant Professor  
Department of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

Michael Leunig, MD, PD, Dr.med.  
Department of Orthopaedics  
Schallthess Clinic  
Zurich, Switzerland

Harlan B. Levine, MD  
Attending Physician  
Department of Orthopaedic Surgery  
Hackensack University Medical Center  
Hackensack, New Jersey

Adolph V. Lombardi, Jr., MD, FACS  
Clinical Assistant Professor  
Department of Orthopaedics  
Department of Biomedical Engineering  
The Ohio State University  
New Albany, Ohio
Roger Cornwall, MD  
Assistant Professor of Orthopaedic Surgery  
University of Cincinnati College of Medicine  
Cincinnati, Ohio

Anna V. Cuomo, MD  
PEDIATRIC ORTHOPAEDIC FELLOW  
Division of Orthopaedic Surgery  
Hospital for Sick Children  
Toronto, Ontario, Canada

Kirk W. Dabney, MD  
Associate Director of the Cerebral Palsy Program  
Alfred I. duPont Hospital for Children  
Wilmington, Delaware

Jon R. Davids, MD  
Chief of Staff  
Director, Motion Analysis Laboratory  
Shriners Hospital for Children  
Greenville, South Carolina

Richard S. Davidson, MD  
Associate Professor  
Division of Pediatric Orthopaedics  
Department of Surgery  
Children’s Hospital of Philadelphia  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

Matthew B. Dobbs, MD  
Associate Professor of Orthopaedic Surgery  
Washington University School of Medicine  
Saint Louis, Missouri

John P. Dormans, MD  
Chief of Orthopaedic Surgery  
The Children's Hospital of Philadelphia  
Philadelphia, Pennsylvania

Denis S. Drummond, MD  
Professor of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Attending Surgeon  
Emeritus Chief of Orthopaedic Surgery  
The Children’s Hospital of Philadelphia  
Philadelphia, Pennsylvania

Craig P. Eberson, MD  
Assistant Professor and Division Chief  
Division of Pediatric Orthopaedics  
Department of Orthopaedics  
Alpert Medical School of Brown University  
Hasbro Children’s Hospital  
Providence, Rhode Island

John B. Emans, MD  
Professor of Orthopedic Surgery  
Children’s Hospital Boston  
Harvard Medical School  
Boston, Massachusetts

Paul W. Esposito, MD  
Professor of Orthopaedic Surgery and Pediatrics  
University of Nebraska Medical Center  
Children’s Hospital and Medical Center  
Omaha, Nebraska

Marybeth Ezaki, MD  
Professor of Orthopaedic Surgery  
Department of Hand Service  
Texas Scottish Rite Hospital for Children  
Dallas, Texas

Reginald S. Fayssoux, MD  
Department of Orthopaedic Surgery  
The Emory Spine Center  
Emory University School of Medicine  
Atlanta, Georgia

Fabio Ferri-De-Barros, MD, FSBOt  
Clinical Fellow, PhD Student  
Department of Orthopaedics  
Hospital for Sick Children  
Toronto, Ontario, Canada

John M. Flynn, MD  
Associate Chief of Orthopaedic Surgery  
The Children’s Hospital of Philadelphia  
Associate Professor of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

Jenny M. Frances, MD, MPH  
Assistant Professor of Orthopaedic Surgery  
New York University Hospital for Joint Diseases  
New York, New York

John Frino, MD  
Assistant Professor of Orthopaedic Surgery  
Wake Forest University School of Medicine  
Winston-Salem, North Carolina

Theodore J. Ganley, MD  
Associate Professor of Orthopaedic Surgery  
University of Pennsylvania School of Medicine  
Attending Surgeon  
Director of Sports Medicine  
The Children’s Hospital of Philadelphia  
Philadelphia, Pennsylvania

Matthew R. Garner, BS  
The Children’s Hospital of Philadelphia  
Philadelphia, Pennsylvania

Purushottam A. Gholve, MD, MBMS, MRCS  
Assistant Professor of Orthopaedics  
Floating Hospital for Children at Tufts Medical Center  
Tufts University School of Medicine  
Boston, Massachusetts

J. Anthony Gonzales, Jr., BS, MD  
Department of Pediatric Orthopedics  
Children’s Hospital of New Orleans  
New Orleans, Louisiana

J. Eric Gordon, MD  
Associate Professor of Medicine  
Department of Orthopedics  
Washington University School of Medicine/St. Louis Children’s Hospital  
St. Louis, Missouri

James T. Guille, MD  
Division of Spinal Disorders  
Brandywine Institute of Orthopedics  
Pottstown, Pennsylvania

Aaron B. Heath, MD  
Division of Orthopaedic Surgery  
The Children’s Hospital of Philadelphia  
Philadelphia, Pennsylvania

Daniel J. Hedequist, MD  
Associate Professor of Orthopedic Surgery  
Department of Orthopedics  
Children’s Hospital Boston/Harvard Medical School  
Boston, Massachusetts

B. David Horn, MD  
Assistant Professor  
Department of Orthopedic Surgery  
University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

Victor Hsu, BA, MD  
Attending Spine Surgeon  
Department of Orthopaedic Surgery  
Orthopaedic Specialty Center  
Willow Grove, Pennsylvania

Lori A. Karol, MD  
Professor of Orthopaedic Surgery  
Texas Scottish Rite Hospital for Children  
Dallas, Texas

Kathryn A. Keeler, MD  
Assistant Professor  
Department of Orthopedic Surgery  
Washington University School of Medicine  
St. Louis, Missouri

Young-Jo Kim, MD, PhD  
Assistant Professor of Orthopaedic Surgery  
Harvard Medical School  
Children’s Hospital Boston  
Boston, Massachusetts

Mininder S. Kocher, MD, MPH  
Associate Director  
Division of Sports Medicine  
Department of Orthopaedic Surgery  
Children’s Hospital Boston  
Associated Professor of Orthopaedic Surgery  
Harvard Medical School  
Harvard School of Public Health  
Boston, Massachusetts

J. Todd R. Lawrence, MD, PhD  
Fellow, Pediatric Orthopaedic Surgery  
The Children’s Hospital of Philadelphia  
Philadelphia, Pennsylvania

Bryan T. Leck, MD  
Fellow  
Department of Orthopedic Surgery  
University of California, San Diego  
San Diego, California

Noppachart Limpaphayom, MD  
Instructor  
Department of Orthopedics  
Chulalongkorn University  
Bangkok, Thailand

Jeffrey E. Martus, MD  
Assistant Professor  
Department of Orthopedics and Rehabilitation  
Vanderbilt Children’s Hospital  
Nashville, Tennessee

Travis H. Matheney, MD  
Instructor in Orthopaedic Surgery  
Harvard Medical School  
Children’s Hospital Boston  
Boston, Massachusetts

James J. McCarthy, MD  
Faculty  
University of Wisconsin School of Medicine and Public Health  
University of Wisconsin Hospital and Clinics  
American Family Children’s Hospital  
Rosemont, Illinois
Richard E. McCarthy, MD
Professor
Chief of Spinal Deformities
Department of Orthopaedics
Arkansas Children’s Hospital
Little Rock, Arkansas

Charles T. Mehlan, DO, MPH
Professor
Department of Pediatric Orthopaedic Surgery
Cincinnati Children’s Hospital Medical Center
Cincinnati, Ohio

Gokce Mik, MD
Department of Orthopaedic Surgery
The Children’s Hospital of Philadelphia
Philadelphia, Pennsylvania

Freeman Miller, MD
Al duPont Hospital for Children
Wilmington, Delaware

Michael B. Millis, MD
Associate Professor of Orthopaedic Surgery
Harvard Medical School
Children’s Hospital Boston
Boston, Massachusetts

Vincent S. Mosca, MD
Associate Professor of Orthopedics
University of Washington School of Medicine
Seattle Children’s Hospital
Seattle, Washington

Scott J. Mubarak, MD
Clinical Professor
Department of Orthopaedics
University of California
San Diego Medical Center
San Diego, California

Stuart M. Myers, MD
Department of Orthopedic Surgery
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Karen S. Myung, MD, PhD
Assistant Professor
Children’s Orthopedic Center
Children’s Hospital of Los Angeles
Los Angeles, California

Unni G. Narayanan, MBBS, MSc, FRCS(C)
Assistant Professor of Surgery
Division of Orthopaedic Surgery
University of Toronto
The Hospital for Sick Children
Toronto, Ontario, Canada

Blaise Nemeth, MA, MS
Assistant Professor (CHS)
Department of Orthopedics
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Kenneth Noonan, MD
Associate Professor
Department of Orthopaedics
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Tom F. Novacheck, MD
Associate Professor
Director, Center for Gait and Motion Analysis
Department of Orthopaedic Surgery
University of Minnesota
Gillette Children’s Specialty Healthcare
St. Paul, Minnesota

Scott N. Oishi, MD
Assistant Professor of Plastic Surgery
Department of Hand Service
Texas Scottish Rite Hospital for Children
Dallas, Texas

Brad Olney, MD
Professor and Chief
Department of Orthopaedics
Children’s Mercy Hospital
Kansas City, Missouri

Norman Y. Otsuka, MD
Clinical Professor
Department of Orthopedic Surgery
University of California, Los Angeles
Shriners Hospitals for Children
Los Angeles, California

Dror Paley, MD, FRSCS
Director
Paley Advanced Limb Lengthening Institute
St. Mary’s Hospital
West Palm Beach, Florida

Kristan A. Pierz, MD
Assistant Professor of Orthopaedics
Connecticut Children’s Medical Center
University of Connecticut School of Medicine
Hartford, Connecticut

Maya E. Pring, MD
Clinical Instructor of Orthopaedic Surgery
University of California San Diego
Rady Children’s Hospital San Diego
San Diego, California

Ellen M. Raney, MD
Clinical Professor of Surgery
Department of Surgery
University of Hawaii John A. Burns School of Medicine
Shriners Hospital for Children
Honolulu, Hawaii

Margaret M. Rich, MD, PhD
Shriners Hospitals for Children—St. Louis
St. Louis, Missouri

James R. Romanowski, MD
Fellow, Orthopaedic Sports Medicine
Department of Orthopaedic Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Anthony A. Scaduto, MD
Pediatric Orthopaedics
Los Angeles Orthopaedic Hospital
Los Angeles, California

David Scher, MD
Associate Professor of Clinical Orthopaedics
Division of Pediatric Orthopaedic Surgery
Department of Orthopaedic Surgery
Weill Cornell School of Medicine
Hospital for Special Surgery
New York, New York

Perry L. Schoenecker, MD
Professor and Chief of Pediatric Orthopaedics
Washington University School of Medicine
Shriners Hospital for Children
St. Louis, Missouri

Tim Schrader, MD
Medical Director, Hip Program
Children’s Healthcare of Atlanta
Atlanta, Georgia

Richard M. Schwend, MD
Professor
Department of Orthopaedics
Children’s Mercy Hospital
Kansas City, Missouri

Eric D. Shirley, MD
Attending Pediatric Orthopaedic Surgery
Bone and Joint Institute
Naval Medical Center Portsmouth
Virginia Beach, Virginia

Om Prasad Shrestha, MBBS
Clinical Fellow
Division of Orthopaedics
The Children’s Hospital of Philadelphia
Philadelphia, Pennsylvania

Ernest L. Sink, MD
Associate Professor
Department of Orthopaedics
The Children’s Hospital
University of Colorado
Aurora, Colorado

David L. Skaggs, MD
Professor of Orthopaedic Surgery
University of Southern California
Chief of Orthopaedic Surgery
Children’s Hospital Los Angeles
Los Angeles, California

Brian G. Smith, MD
Associate Professor of Orthopaedics and Rehabilitation
Director, Yale Pediatric Orthopaedics and Rehabilitation
Yale School of Medicine
New Haven, Connecticut

Brian Snyder, MD, PhD
Associate Professor
Department of Orthopaedic Surgery
Harvard Medical School
Children’s Hospital Boston
Boston, Massachusetts

David A. Spiegel, MD
Assistant Professor of Orthopaedic Surgery
Children’s Hospital of Philadelphia
University of Philadelphia School of Medicine
Philadelphia, Pennsylvania

Shawn C. Standard, MD
Head of Pediatric Orthopedics
International Center for Limb Lengthening
Rubin Institute for Advanced Orthopedics
Sinai Hospital of Baltimore
Baltimore, Maryland

Anthony A. Stans, MD
Assistant Professor of Medicine
Chair, Division of Pediatric Orthopedics
Mayo Clinic
Rochester, Minnesota
PART 5 ONCOLOGY

Adesegun Abudu, FRCS
Royal Orthopaedic Hospital Oncology Service
Northfield, Birmingham, United Kingdom

Aharon Amir, MD
Attending Surgeon
Department of Plastic Surgery
Tel-Aviv Sourasky Medical Center
Tel-Aviv, Israel

Jacob Bickels, MD
Head, Service for the Management of Metastatic Bone Disease
Attending Surgeon, National Unit of Orthopedic Oncology
Tel-Aviv Sourasky Medical Center
Professor of Orthopedic Surgery
Sackler School of Medicine, Tel-Aviv University
Tel-Aviv, Israel

Loretta B. Chou, MD
Professor of Orthopaedic Surgery
Stanford University
Chief, Foot and Ankle Service
Lucile Packard Children’s Hospital at Stanford
Palo Alto, California

Ernest U. Conrad III, MD
Professor of Orthopaedics
University of Washington
Director, Bone Tumor Clinic
Children’s Hospital and Regional Medical Center
Seattle, Washington

Jeffrey J. Eckardt, MD
Director, Orthopaedic Oncology
UCLA Santa Monica Orthopaedic Center
Santa Monica, California

Steven Gitelis, MD
Professor and Vice Chairman of Orthopaedic Surgery
Director, Section of Orthopaedic Oncology
Rush University Medical Center
Chicago, Illinois

Robert Grimer, FRCS
Consultant Orthopaedic Surgeon
Royal Orthopaedic Hospital
Northfield, Birmingham, United Kingdom

Eyal Gur, MD
Director, Unit of Microsurgery
Department of Plastic Surgery
Tel-Aviv Sourasky Medical Center
Senior Lecturer
Sackler School of Medicine
Tel-Aviv University
Tel-Aviv, Israel

Lee Jeys, MB, ChB, MSc, FRCS
Consultant Orthopaedic Surgeon
Specialist in Hip, Knee, and Oncology Surgery
Midland Hip & Knee Clinic
Royal Orthopaedic Hospital
Northfield, Birmingham, United Kingdom

Robert M. Henshaw, MD
Associate Clinical Professor of Orthopaedic Surgery
Georgetown University Medical Center
Director, Orthopaedic Oncology
Director, Fellowship Program in Orthopaedic Oncology
Washington Cancer Institute
Washington, District of Columbia

Yvette Ho
Research Assistant
Washington Musculoskeletal Tumor Center
Washington Cancer Institute
Washington, District of Columbia

Norio Kawahara, MD, PhD
Clinical Professor
Department of Orthopaedic Surgery
Kanazawa University School of Medicine
Ishikawa, Japan

Kristen Kellar-Graney, MS
Tumor Biologist and Clinical Research Coordinator
Washington Cancer Institute
Washington, District of Columbia

Piya Kiatsiri, MD
Orthopaedic Oncology Unit
Institute of Orthopedics
Lerdos Hospital
Bangkok, Thailand

Yehuda Koller, MD
Attending Surgeon, National Unit of Orthopedic Oncology
Tel-Aviv Sourasky Medical Center
Senior Lecturer
Sackler School of Medicine, Tel-Aviv University
Tel-Aviv, Israel

Jennifer Lisle, MD
Assistant Professor of Orthopedics, Rehabilitation, and Pediatrics
University of Vermont College of Medicine
Vermont Children’s Hospital at Fletcher Allen Health Care
Burlington, Vermont

Martin M. Malawer, MD, FACS
Professor (Clinical Scholar) of Orthopaedics
Professor of Pediatrics (Hematology and Oncology)
Georgetown University Medical Center
Professor of Orthopaedic Surgery
George Washington University
Director of Research and Development
Orthopaedic Oncology
Washington Cancer Institute
Orthopaedic Oncology
Children’s National Medical Center
Washington, District of Columbia
Consultant (Pediatric and Surgery Branch)
National Cancer Institute, National Institutes of Health
Bethesda, Maryland

Isaac Meller, MD
Director, National Unit of Orthopedic Oncology
Tel-Aviv Sourasky Medical Center
Professor of Orthopedic Surgery
Sackler School of Medicine, Tel-Aviv University
Tel-Aviv, Israel

Benjamin J. Miller, MD
Rush Orthopaedic Oncology
Rush University Medical Center
Chicago, Illinois

Hideki Murakami, MD
Professor of Orthopedic Surgery
Tel-Aviv, Israel

Yves van Heest, MD
Professor of Orthopaedic Surgery
University of Minnesota
Minneapolis, Minnesota

Thanapong Waitayawinyu, MD
Assistant Professor of Orthopaedics
Thammasat University
Klonghuang, Pathumthani, Thailand

Eric J. Wall, MD
Director of Orthopaedic Surgery
Cincinnati Children’s Hospital Medical Center
Cincinnati, Ohio

Lawrence Wells, MD
Assistant Professor of Orthopaedic Surgery
University of Pennsylvania School of Medicine
Children’s Hospital of Philadelphia
Philadelphia, Pennsylvania

Dennis R. Wenger, MD
Clinical Professor of Orthopaedic Surgery
University of California San Diego
Rady Children’s Hospital San Diego
San Diego, California

Roger F. Widmann, MD
Associate Professor of Clinical Orthopaedic Surgery
Division of Pediatric Orthopaedic Surgery
Weill Cornell Medical College
Hospital for Special Surgery
New York, New York

Jennifer J. Winell, MD
Assistant Professor of Orthopaedic Surgery
Children’s Hospital of Philadelphia
Philadelphia, Pennsylvania

Yi-Meng Yen, MD, PhD
Instructor in Orthopaedic Surgery
Harvard Medical School
Orthopaedic Surgery/Sports Medicine
Children’s Hospital Boston
Boston, Massachusetts
PART 6 HAND, WRIST, AND FOREARM

Brian D. Adams, MD
Professor of Orthopaedic Surgery and Bioengineering
University of Iowa
Iowa City, Iowa

Christopher H. Allan, MD
Associate Professor of Orthopaedics and Sports Medicine
University of Washington
Seattle, Washington

Edward A. Athanasian, MD
Associate Professor of Clinical Orthopaedic Surgery
Weill Cornell Medical College
Associate Attending Orthopaedic Surgeon
Hospital for Special Surgery
New York, New York

Mark N. Awantang, MD
Orthopaedic Associates
Washington, District of Columbia

Alejandro Badia, MD, FACS
Badia Hand to Shoulder Center
Chief of Hand Surgery
Baptist Hospital
Miami, Florida

Mark E. Baratz, MD
Professor and Executive Vice Chairman
Chief, Upper Extremity Service
Department of Orthopaedic Residency and Upper Extremity Fellowship
Drexel University College of Medicine
Allegheny General Hospital
Pittsburgh, Pennsylvania

Asheesh Bedi, MD
Assistant Professor of Orthopaedic Surgery
University of Michigan Health System
Ann Arbor, Michigan

Michael S. Bednar, MD
Professor of Orthopaedic Surgery and Rehabilitation
Stritch School of Medicine
Loyola University–Chicago
Maywood, Illinois

Kerry Bemers, CHT
University Orthopedics
Providence, Rhode Island

Leon S. Benson, MD
Professor of Clinical Orthopaedic Surgery
University of Chicago Pritzker School of Medicine
Illinois Bone and Joint Institute
Glencoe, Illinois

Pedro K. Beredjiklian, MD
Associate Professor of Orthopaedic Surgery
Thomas Jefferson School of Medicine
Chief, Hand Surgery Division
The Rothman Institute
Philadelphia, Pennsylvania

Randy R. Bindra, MD
Professor of Orthopaedic Surgery
Loyola University Medical Center
Maywood, Illinois

Philip E. Blazar, MD
Assistant Professor of Orthopaedic Surgery
Brigham and Women’s Hospital
Boston, Massachusetts

Michael R. Boland, MBChB, FRCS, FRACS
Assistant Professor of Orthopaedic Surgery
University of Kentucky College of Medicine
Lexington, Kentucky

Benjamin J. Boudreaux, MD
Assistant Clinical Professor of Plastic Surgery
Louisiana State University
Baton Rouge, Louisiana

Martin I. Boyer, MD
Carole B. and Jerome T. Loeb Professor of Orthopaedic Surgery
Department of Orthopaedic Surgery
Washington University School of Medicine
St. Louis, Missouri

David J. Bozentka, MD
Associate Professor of Orthopaedic Surgery
University of Pennsylvania
Chief, Orthopaedic Surgery
Penn Presbyterian Medical Center
Philadelphia, Pennsylvania

Jay T. Bridgeman, MD
Assistant Professor of Orthopaedics
Penn State Hershey Bone and Joint Institute
Hershey, Pennsylvania

John S. Buchieri, MD
Private Practice, Lake Health
Willoughby, Ohio

Jeffrey E. Budoff, MD
Director, Orthopaedic Hand and Upper Extremity Service
Houston VA Medical Center
Southwest Orthopaedic Group
Houston, Texas

Reuben A. Bueno, Jr., MD
Assistant Professor of Plastic Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

John T. Capo, MD
Associate Professor of Orthopaedics
Chief, Division of Hand and Microvascular Surgery
UMDNJ-New Jersey Medical School
Newark, New Jersey

Charles Cassidy, MD
Henry H. Banks Associate Professor and Chairman
Tufts University School of Medicine
Orthopaedist in Chief at Tufts Medical Center
Boston, Massachusetts
Louis W. Catalano III, MD
Assistant Clinical Professor
Columbia University
C. V. Staff
Hand Surgery Center
Roosevelt Hospital
New York, New York

Edwin Y. Chang, MD
Spokane Plastic Surgeons
Spokane, Washington

Nilesh M. Chaudhari, MD
Assistant Professor of Surgery
Department of Orthopaedic Surgery
University of Alabama, Birmingham
Birmingham, Alabama

Neal C. Chen, MD
Clinical Instructor
Department of Orthopaedic Surgery
University of Michigan
Ann Arbor, Michigan

Andrew Chin, MD FRCS
Consultant Hand Surgeon
Hand Surgery Unit
Singapore General Hospital
Singapore

Kevin C. Chung, MD, MS
Professor of Surgery
Section of Plastic Surgery
University of Michigan
Ann Arbor, Michigan

Evan D. Collins, MD
Assistant Professor of Orthopaedics
Weill Cornell Medical College
New York, New York
Staff Physician
Department of Orthopaedics
The Methodist Hospital
Houston, Texas

Cari Cordell, MD
Fellow
Department of Orthopaedics
Loyola University Medical Center
Maywood, Illinois

Andrew W. Cross, DVM, MD
Hand Surgery Specialists, Inc.
Cincinnati, Ohio

Randall W. Culp, MD
Professor of Orthopaedic Hand and
Microsurgery
Department of Orthopaedics
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Catherine M. Curtin, MD
Assistant Professor of Plastic Surgery
Stanford University
Pal Alto, California

Leonard L. D’Addesi, MD
Orthopaedic Associates of Reading
Reading Hospital and Medical Center
West Reading, Pennsylvania

Jorge de la Torre, MD
Professor of Surgery
Chief, Plastic Surgery
Division of Plastic Surgery
Department of Surgery
University of Alabama at Birmingham
Birmingham VA Medical Center
Birmingham, Alabama

Anthony M. DeLuise, Jr., MD
Fellow
Department of Orthopaedic Surgery
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Edward Diao, MD
Professor Emeritus of Orthopaedic Surgery and Neurosurgery
University of California, San Francisco
San Francisco, California

John A. Dilger, MD
Department of Anesthesiology
Mayo Clinic
Rochester, Minnesota

Christopher Doumas, MD
Clinical Assistant Professor of Orthopaedic Surgery
Robert Wood Johnson Medical School
University of Medicine and Dentistry of New Jersey
New Brunswick, New Jersey

John C. Elfar, MD
Assistant Professor
Department of Orthopaedics
University of Rochester
Rochester, New York

Peter J. Evans, MD, PhD, FRCS
Director, Hand and Upper Extremity
Department of Orthopaedics
Cleveland Clinic
Cleveland, Ohio

Paul Feldon, MD
Clinical Associate Professor of Orthopaedics
Tufts University School of Medicine
New England Baptist Hospital
Boston, Massachusetts

Diego Fernandez, MD
Lindenhof Hospital
Bern, Switzerland

John J. Fernandez, MD
Assistant Professor of Orthopaedic Surgery
Division of Hand, Wrist, and Elbow
Rush University Medical Center
Chicago, Illinois

Angel Ferreres, MD, PhD
Consultant Hand Surgeon
Hand Surgery Unit
Institut Kaplan
Barcelona, Spain

Rimma Finkel, MD
Chandler, Arizona

Christian Ford, MD
Chief Resident
Department of Plastic Surgery
Stanford Hospitals and Clinics
Palo Alto, California

Christopher L. Forthman, MD
Consultant, Curtis National Hand Center
Department of Orthopaedic Surgery
Union Memorial Hospital
Baltimore, Maryland

Jeffrey B. Friedrich, MD
Assistant Professor of Surgery and Orthopedics (Adjunct)
University of Washington
Seattle, Washington

Marc Garcia-Elias, MD, PhD
Consultant Hand Surgeon
Hand Surgery Unit
Institut Kaplan
Barcelona, Spain

William B. Geissler, MD
Professor and Chief
Division of Hand and Upper Extremity Surgery
Chief
Arthroscopic Surgery and Sports Medicine
Department of Orthopaedic Surgery and Rehabilitation
University of Mississippi Medical Center
Jackson, Mississippi

Harris Gellman, MD
Voluntary Professor
Department of Orthopedic and Plastic Surgery
University of Miami
Miami, Florida

Grey Giddins, MBBch, FRCS(Orth), EDHS
Consultant Orthopaedic and Hand Surgeon
Department of Orthopaedics
Royal United Hospital
Bath, England

Steven Z. Glickel, MD
Clinical Professor of Orthopaedic Surgery
C. V. Staff
Hand Surgery Center
Roosevelt Hospital
New York, New York

Charles A. Goldfarb, MD
Associate Professor
Department of Orthopaedic Surgery
Washington University School of Medicine
St. Louis, Missouri

Mark Golemski, MD
Resident of Internal Medicine
UT Southwestern Medical Center
Dallas, Texas

Christopher R. Goll, MD
Heckin Orthopaedics
Jacksonville, Florida

Thomas J. Graham, MD
Associate Professor
Department of Orthopaedic Surgery
Department of Plastic Surgery
Johns Hopkins School of Medicine
Chief, The Curtis National Hand Center
Vice-Chair, Department of Orthopaedic Surgery
Director, MedStar SportsHealth
Founder and Surgeon-in-Chief, Arnold Palmer SportsHealth Center
Union Memorial Hospital
Baltimore, Maryland

Jennifer Green, MD
Hand and Upper Extremity Surgeon
Newton Wellesley Orthopaedic Association
Newton, Massachusetts
Jeffrey A. Greenberg, MD, MS
Clinical Assistant Professor
Department of Orthopedics
Indiana University
Indiana Hand Center
Indianapolis, Indiana

Warren C. Hammert, MD
Associate Professor of Orthopaedic Surgery
Department of Orthopaedic Surgery and Plastic Surgery
University of Rochester Medical Center
Rochester, New York

Douglas P. Hanel, MD
Professor of Orthopaedics and Sports Medicine
University of Washington
Head, Pediatric Hand Surgery Program
Seattle, Washington

Scott L. Hansen, MD
Assistant Professor of Surgery
Division of Plastic and Reconstructive Surgery
University of California, San Francisco
San Francisco, California

Timothy W. Harman, BA, DO
Associate Clinical Professor
Assistant Program Director
Department of Orthopedics
Ohio University
Dayton, Ohio

Colin Harris, MD
Department of Orthopaedics
UMDNJ-New Jersey Medical School
Newark, New Jersey

Mark F. Hendrickson, MD
Section Head, Hand Surgery
Cleveland Clinic
Cleveland, Ohio

Carlos Heras-Palou, MD, FRCS(Trau&Orth)

Assistant Professor
Department of Plastic Surgery
The University of Texas/MC Anderson
Cancer Center
Houston, Texas

Rodrigo Santamarina, MD
Plastic Surgeon
Fellowship-trained Hand Surgeon
Assistant Professor of Surgery
University of Massachusetts
Berkshire Medical Center
Pittsfield, Massachusetts

Keith A. Segalman, MD
Assistant Professor of Orthopaedic Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
Greater Chesapeake Hand Specialists
Lutherville, Maryland

David B. Shapiro, MD
Section of Hand and Upper Extremity
Surgery
Department of Orthopaedic Surgery
The Cleveland Clinic
Cleveland, Ohio

Joseph M. Sherrill, MD
Chairman of Surgery
Healthsouth Medical Center
Alabama Orthopaedic Institute
Birmingham, Alabama

Alexander Y. Shin, MD
Professor of Orthopedic Surgery
Mayo Clinic
Rochester, Minnesota

Joseph F. Slade III, MD†
Professor of Orthopaedics and Plastic
Surgery
Department of Orthopaedics and
Rehabilitation
Yale University School of Medicine
Guilford, Connecticut

Robert R. Slater, Jr., MD
Associate Clinical Professor
Department of Orthopaedic Surgery
University of California, Davis
Folsom, California

David J. Slutsky, MD, FRCS(G)
Assistant Clinical Professor
David Geffen UCLA School of Medicine
Chief of Reconstructive Hand Surgery
Department of Orthopaedics
Harbor-UCLA Medical Center
The Hand and Wrist Institute
Torrance, California

Hugh M. Smith, MD
Assistant Professor of Anesthesiology
Mayo Clinic
Rochester, Minnesota

Dean G. Sotereanos, MD
Professor of Orthopaedic Surgery
Drexel University College of Medicine
Allegheny General Hospital
Pittsburgh, Pennsylvania

Edwin E. Spencer, Jr., MD
Attending Surgeon
Shoulder and Elbow Center
Knoxville Orthopaedic Clinic
Knoxville, Tennessee

Rena L. Stewart, MD
Assistant Professor
Department of Surgery/Orthopaedics
University Hospital (University of Alabama)
Birmingham, Alabama

Robert J. Strauch, MD
Professor of Clinical Orthopaedic Surgery
Columbia University Medical Center
New York, New York

James W. Strickland, MD
Clinical Professor of Orthopaedic Surgery
Indiana University School of Medicine
Reconstructive Hand Surgeons of Indiana
Carmel, Indiana

Eric Stuffmann, MD
Chief Resident of Orthopaedic Surgery
Stanford University Medical Center
Redwood City, California

Robert M. Szabo, MD, MPH
Professor of Orthopaedic Surgery and
Plastic Surgery
Chief, Hand, Upper Extremity, &
Microvascular Surgery
Department of Orthopaedic Surgery
University of California, Davis School of
Medicine
Sacramento, California

Jane S. Tan, MD
Department of Orthopaedic Surgery
Kaiser Permanente
Denver, Colorado

John S. Taras, MD
Associate Professor
Department of Orthopaedic Surgery
Thomas Jefferson University
Chief, Division of Hand and Surgery
Associate Professor
Department of Orthopaedic Surgery
Drexel University
Philadelphia, Pennsylvania

Andrew L. Terrono, MD
Clinical Professor of Orthopaedics
Tufts University School of Medicine
New England Baptist Hospital
Boston, Massachusetts

Joseph J. Thoder, MD
Professor
Department of Orthopaedic Surgery
Temple University Hospital
Philadelphia, Pennsylvania

Christopher J. Thomson, MD
Birmingham, Alabama

E. Bruce Toby, MD
Department of Orthopaedic Surgery
The University of Kansas Hospital
Kansas City, Kansas

Matthew M. Tomaino, MD
Tomaino Orthopaedic Care for Shoulder,
Hand, & Elbow
Rochester General Health System
Rochester, New York

Thomas Trumble, BA, MD
Professor and Chief, Hand and Upper
Extremity Surgery
Department of Orthopaedics/Sports
Medicine
University of Washington School of
Medicine
Seattle, Washington

Richard L. Uhl, MD
Professor of Surgery
Division of Orthopaedic Surgery
Albany Medical College
Albany, New York

Thomas F. Varecka, MD
Assistant Professor of Orthopaedic Surgery
University of Minnesota
Director, Hand and Microsurgery
Hennepin County Medical Center
Minneapolis, Minnesota

Luis O. Vasconez, MD
Professor of Surgery
Division of Plastic Surgery
University of Alabama at Birmingham
Birmingham, Alabama

John J. Walsh IV, MD
Associate Professor
Department of Orthopaedics
University of South Carolina School of
Medicine
Columbia, South Carolina

Christina M. Ward, MD
Department of Orthopaedic Surgery
University of Minnesota
Minneapolis, Minnesota

† deceased
Lance G. Warhold, MD
Division Director, Upper Extremity
Department of Orthopaedic Surgery
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire

Arnold-Peter Weiss, MD
R. Scot Sellers Scholar of Hand Surgery
Professor of Orthopaedics
Associate Dean of Medicine
Brown University Medical School
Providence, Rhode Island

Mark Wilczynski, MD
Department of Orthopaedic Surgery
Washington University School of Medicine
St. Louis, Missouri

D. Patrick Williams, DO
Hand Microsurgery & Reconstructive Orthopaedics
Erie, Pennsylvania

Rafael M. M. Williams, MD
Wilson, Wyoming

Andrew Wong, MD
Private Practice
Arrowhead Orthopaedics
Redlands, California
Assistant Professor—Clinical
Department of Orthopaedic Surgery
Loma Linda University
Loma Linda, California

Jeffrey Yao, MD
Assistant Professor
Department of Orthopaedic Surgery
Stanford University Medical Center
Redwood City, California

Elvin G. Zook, MD
Professor Emeritus
Division of Plastic Surgery
Department of Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

PART 7 SHOULDER AND ELBOW

Joseph A. Abboud, MD
Clinical Assistant Professor of Orthopaedic Surgery
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Aymeric André, MD
Resident
Department of Plastic Surgery
University Hospital Rangueil
Paul-Sabatier University
Toulouse, France

Carl Basamania, MD, FACS
The Polyclinic First Hill
Seattle, Washington

Robert H. Bell, MD
Associate Professor of Orthopaedics
Crystal Clinic
Orthopaedic Surgeons, Inc.
Akron, Ohio

Ryan T. Bicknell, MD, MSc, FRCS(C)
Assistant Professor of Orthopaedic Surgery
Queen’s University
Kingston General Hospital
Kingston, Ontario, Canada

Louis U. Bigliani, MD
Frank E. Stinchfield Professor and Chairman of Orthopedic Surgery
Columbia University
Director of the Orthopedic Surgery Service
New York-Presbyterian Hospital/Columbia University Medical Center
New York, New York

Theodore A. Blaine, MD
Associate Professor of Orthopaedic Surgery
Brown Alpert Medical School
Rhode Island Hospital
Providence, Rhode Island

Kamal I. Bohnsali, MD
Attending Orthopaedic Surgeon, Shoulder and Elbow Reconstructive Orthopaedics
Department of Orthopaedics
Memorial Hospital
St. Luke’s Hospital
St. Vincent’s Hospital
Jacksonville, Florida

Nicolas Bonneville, MD
Clinical Assistant in Orthopedic Surgery
Department of Orthopaedics and Traumatology
University Hospital Purpan
Paul-Sabatier University
Toulouse, France

Christopher T. Born, MD
Professor of Orthopaedic Surgery
The Warren Alpert Medical School of Brown University
Rhode Island Hospital
Providence, Rhode Island

Joanna G. Branstetter, MD
Orthopaedic Surgeon
Madigan Army Medical Center
San Antonio, Texas

Juan Castellanos-Rosas, MD
Orthopaedic Surgeon
Department of Trauma Surgery
Hospital General Regional
Col Girasoles, Coyoacán, Mexico

Michael J. Cossu, MD
Department of Orthopaedic Surgery
University Hospital Rangueil
Paul-Sabatier University
Toulouse, France

Mark S. Cohen, MD
Professor and Director
Section of Hand and Elbow Surgery
Rush University Medical Center
Chicago, Illinois

J. Dean Cole, MD
Medical Director
Florida Hospital Orthopaedic Institute Fracture Care Center
Orlando, Florida

Patrick M. Conner, MD
Clinical Assistant Professor of Orthopaedic Surgery
Brigham and Women’s Hospital
Boston, Massachusetts

Thomas P. Goss, MD
Professor of Orthopaedic Surgery
Department of Orthopaedics and Physical Rehabilitation
University of Massachusetts Medical School
Worcester, Massachusetts
Andrew Green, MD  
Associate Professor of Orthopaedic Surgery  
Brown Alpert Medical School  
Chief, Shoulder and Elbow Surgery  
Providence, Rhode Island  

George Frederick Hatch III, MD  
USC Orthopaedic Surgery Associates  
Los Angeles, California  

Laurence D. Higgins, MD  
Associate Professor  
Chief, Sports Medicine and Shoulder Service  
Department of Orthopedic Surgery  
Brigham & Women’s Hospital  
Boston, Massachusetts  

Joseph P. Iannotti, MD, PhD  
Maynard Madden Professor of Orthopaedic Surgery  
Chairman, Orthopaedic and Rheumatologic Institute  
The Cleveland Clinic  
Cleveland, Ohio  

Asif M. Ilyas, MD  
Director, Temple Hand Center  
Assistant Professor, Orthopaedic Surgery  
Temple University Hospital  
Philadelphia, Pennsylvania  

John M. Itamura, MD  
Associate Professor  
Department of Orthopaedic Surgery  
University of Southern California  
Keck School of Medicine  
Los Angeles, California  

Jesse B. Jupiter, MD  
Hanstorg Wyss/AO Professor of Orthopaedic Surgery  
Harvard Medical School  
Chief, Hand and Upper Limb Service  
Massachusetts General Hospital  
Boston, Massachusetts  

Steven P. Kalandiak, MD  
Assistant Professor of Clinical Orthopaedics  
University of Miami  
Miami, Florida  

Srith Kamieni, MBCh, BSc(Hons), FRCS-Orth  
Associate Professor of Elbow and Shoulder Surgery  
Professor of Bioengineering  
Department of Sports, Orthopaedics, and Trauma  
Kentucky Clinic  
University of Kentucky  
Lexington, Kentucky  

Leonid I. Katolik, MD  
Philadelphia Hand Center  
Philadelphia, Pennsylvania  

Graham J. W. King, MD, MSc, FRCS  
Professor of Surgery  
Division of Orthopaedic Surgery  
University of Western Ontario  
Hand and Upper Limb Centre  
St. Joseph’s Health Centre  
London, Ontario, Canada  

Raymond A. Klug, MD  
Assistant Staff  
Department of Orthopaedic Surgery  
Los Alamitos Medical Center  
Los Alamitos, California  

Thomas J. Kovack, DO  
Department of Orthopaedic Surgery  
Doctors Hospital  
Hillard, Ohio  

Suman G. Krishnan, MD  
Fellowship Director  
Department of Shoulder Service  
The Carrell Clinic  
Dallas, Texas  

John E. Kuhn, MD  
Associate Professor  
Chief of Shoulder Surgery  
Department of Orthopaedics and Rehabilitation  
Vanderbilt University Medical Center  
Nashville, Tennessee  

Phillip Langer, MD, MS  
Assistant Team Physician and Orthopedic Surgeon  
NFL Atlanta Falcons  
NHL Atlanta Thrashers  
Atlanta Sports Medicine & Orthopedic Center  
Atlanta, Georgia  

Jonathan H. Lee, MD  
Fellow in Adult Reconstruction  
Department of Orthopaedic Surgery  
Hospital for Special Surgery  
New York, New York  

William N. Levine, MD  
Vice Chairman and Professor  
Residency Director and Director of Sports Medicine  
Department of Orthopaedic Surgery  
Columbia University Medical Center  
New York, New York  

Steven B. Lippitt, MD  
Professor of Orthopaedic Surgery  
Northeastern Ohio Universities College of Medicine  
Akron General Medical Center  
Akron, Ohio  

Bryan J. Loeffer, MD  
Department of Orthopaedic Surgery  
Carolinas Medical Center  
Charlotte, North Carolina  

John Lunn, FRCSI  
Department of Orthopaedics  
Hermitage Medical Clinic  
Dublin, Ireland  

Pierre Mansat, MD, PhD  
Professor of Orthopedic Surgery  
Department of Orthopedics and Traumatology  
University Hospital Purpan  
Paul-Sabatier University  
Toulouse, France  

Frederick A. Matsen III, MD  
Professor and Chair  
Department of Orthopaedics and Sports Medicine  
University of Washington  
Seattle, Washington  

Jesse A. McCarron, MD  
Associate Professor  
Department of Orthopaedic Surgery  
The Cleveland Clinic  
Cleveland, Ohio  

Michael D. McKee, MD, FRCS(c)  
Professor  
Division of Orthopaedics  
Department of Surgery  
University of Toronto  
Toronto, Ontario, Canada  

Mark A. Migelli, MD  
Associate Director of Shoulder and Elbow Fellowship  
Florida Orthopaedic Institute  
Associate Professor  
Department of Upper Extremity Surgery  
University of South Florida  
Tampa, Florida  

Steven Milos, MD  
Department of Orthopaedics  
Swedish American Hospital  
Rockford, Illinois  

Anthony Miniaci, MD, FRCS  
Professor of Surgery  
Cleveland Clinic Lerner College of Medicine  
Head, Sports Medicine  
Cleveland Clinic Sports Health Center  
Orthopaedic and Rheumatologic Institute  
Garfield Heights, Ohio  

Anand M. Murthi, MD  
Assistant Professor of Orthopaedics  
Chief of Shoulder and Elbow Service  
Department of Orthopaedics  
University of Maryland School of Medicine  
Baltimore, Maryland  

Andrew S. Neviser, MD  
Resident  
Department of Orthopaedic Surgery  
Hospital for Special Surgery  
New York, New York  

Robert J. Neviser, MD  
Professor and Chairman  
Department of Orthopaedic Surgery  
George Washington University  
Washington, District of Columbia  

Daniel D. Noble, BA  
Research Assistant  
Crystal Clinic  
Orthopaedic Surgeons, Inc.  
Akron, Ohio  

Jeffrey S. Noble, MD  
Associate Professor of Orthopaedics  
Crystal Clinic  
Orthopaedic Surgeons, Inc.  
Akron, Ohio
Brett D. Owens, MD  
Assistant Professor  
Department of Orthopaedic Surgery  
Service  
Keller Army Hospital  
West Point, New York

Bradford O. Parsons, MD  
Assistant Professor of Orthopaedic Surgery  
Mount Sinai Medical Center  
New York, New York

Jubin B. Payandeh, MD, FRCS(c)  
Staff Surgeon  
Department of Surgery  
Big Thunder Orthopaedics  
Thunder Bay, Ontario, Canada

Alexander H. Payatakes, MD  
Assistant Professor  
Hand and Wrist Service  
Department of Orthopaedics  
Penn State College of Medicine  
Penn State Milton S. Hershey Medical Center  
Hershey, Pennsylvania

Matthew D. Pepe, MD  
Sports Medicine Surgeon  
The Rothman Institute  
Voorhees, New Jersey

Matthew L. Ramsey, MD  
Associate Professor of Orthopaedic Surgery  
Rothman Institute Shoulder and Elbow Surgery  
Thomas Jefferson University  
Philadelphia, Pennsylvania

Michael A. Rauh, MD  
Clinical Assistant Professor of Orthopaedic Surgery  
State University of New York at Buffalo  
Buffalo, New York

David Ring, MD, PhD  
Associate Professor of Orthopaedic Surgery  
Harvard Medical School  
Department of Orthopaedic Surgery  
Massachusetts General Hospital  
Boston, Massachusetts

Robin R. Richards, MD, FRCSC  
Professor  
Department of Surgery  
University of Toronto  
Sunnybrook Health Sciences Center  
Toronto, Ontario, Canada

Charles A. Rockwood, MD  
Professor and Chairman Emeritus of Orthopaedics  
The University of Texas Health Science Center at San Antonio  
San Antonio, Texas

Associate Professor of Orthopaedic Surgery  
Director, Section of Shoulder & Elbow  
Rush University Medical Center  
Chicago, Illinois

Yishai Rosenblatt, MD  
Orthopaedic Surgeon  
Hand and Upper Limb Surgeon  
The Unit of Hand Surgery and Orthopaedic Surgery  
Tel-Aviv Sourasky Medical Center  
The Sackler Faculty of Medicine  
Tel-Aviv University  
Tel-Aviv, Israel

Joaquin Sanchez-Sotelo, MD, PhD  
Associate Professor  
Department of Orthopedic Surgery  
Mayo Clinic  
Rochester, Minnesota

Shadley C. Schiffern, MD  
Attending Orthopaedic Surgeon  
NorthEast Orthopedics, PA  
Concord, North Carolina

Ryan W. Simovitch, MD  
Shoulder and Elbow Service  
Palm Beach Orthopaedic Institute  
Palm Beach Gardens, Florida

Anshu Singh, MD  
Shoulder and Elbow Surgeon  
Kaiser Permanente  
San Diego, California

Dean G. Sotereanos, MD  
Professor of Orthopaedic Surgery  
Drexel University College of Medicine  
Allegheny General Hospital  
Pittsburgh, Pennsylvania

Edwin E. Spencer, Jr., MD  
Knoxville Orthopaedic Clinic  
Knoxville, Tennessee

Jason A. Stein, MD  
Assistant Professor  
Department of Orthopaedics  
University of Maryland  
Baltimore, Maryland

Scott P. Steinmann, MD  
Professor of Orthopaedics  
Mayo Clinic  
Rochester, Minnesota

Bradford S. Tucker, MD  
Clinical Instructor  
Department of Orthopaedic Surgery  
Thomas Jefferson University Hospital  
Egg Harbor Township, New Jersey

Gilles Walch, MD  
Department of Shoulder Surgery  
Centre Orthopédique Santy  
Hôpital Privé J Mermoz  
Lyon, France

Jon J. P. Warner, MD  
Chief, The Harvard Shoulder Service  
Professor of Orthopaedics  
Massachusetts General Hospital  
Boston, Massachusetts

Brent B. Wiesel, MD  
Chief, Shoulder Service  
Department of Orthopaedic Surgery  
Georgetown University Hospital  
Washington, District of Columbia

Gerald R. Williams, MD  
Professor of Orthopaedic Surgery  
Chief, Shoulder and Elbow Service  
The Rothman Institute  
Jefferson Medical College  
Philadelphia, Pennsylvania

Michael A. Wirth, MD  
Professor of Orthopaedics  
The Charles A. Rockwood, Jr., MD Chair  
University of Texas Health Science Center  
San Antonio, Texas

PART 8 FOOT AND ANKLE

Jorge I. Acevedo, MD  
Associate Clinical Faculty  
Department of Orthopedic Surgery  
University of Miami  
Wellington Regional Medical Center  
Royal Palm Beach, Florida

Samuel B. Adams, Jr., MD  
Resident  
Department of Orthopaedic Surgery  
Duke University Medical Center  
Durham, North Carolina

Robert S. Adelaar, MD  
Medical College of Virginia  
Richmond, Virginia

Oladapo Alade, MD  
Private Practice  
Houston, Texas

Richard Alvarez, MD  
Southern Orthopedic Foot Center  
Chattanooga, Tennessee

Annunziato Amendola, MD  
Professor and Callaghan Chair  
Department of Orthopaedic Surgery  
University of Iowa  
Iowa City, Iowa

John G. Anderson, MD  
Associate Professor  
Michigan State University College of Human Medicine  
Co-Director  
Grand Rapids Orthopaedic Foot and Ankle Fellowship  
Assistant Program Director  
Grand Rapids Orthopaedic Residency Program  
Orthopaedic Associates of Michigan  
Grand Rapids, Michigan

Robert B. Anderson, MD  
Chief, Foot and Ankle Service  
Department of Orthopaedic Surgery  
Carolinas Medical Center, OrthoCarolina  
Charlotte, North Carolina

Department of Orthopaedic Surgery
University of Manitoba
Winnipeg, Manitoba, Canada

Douglas N. Beaman, MD
Clinical Assistant Professor
Department of Orthopaedic Surgery
Oregon Health Sciences University
Summit Orthopaedics
Portland, Oregon

Christoph Becher, MD
Department of Orthopaedic Surgery
Hannover Medical School
Hannover, Germany

Karl Bergmann, MD
Department of Orthopaedics
University of Medicine and Dentistry of New Jersey
NJ Medical School
Newark, New Jersey

Gregory C. Berlet, MD, FRCS(C)
Chief, Foot and Ankle Surgery
Orthopaedic Foot and Ankle Center
Ohio State University
Westerville, Ohio

James L. Beskin, MD
Clinical Assistant Professor
Department of Orthopedics
Tulane University
Director, Foot & Ankle Section
Orthopedic Residency Program
Atlanta Medical Center
Atlanta, Georgia

Eric M. Bluman, MD, PhD
Assistant Professor
Department of Orthopaedic Surgery
Harvard University
Brigham and Women’s Hospital
Boston, Massachusetts

Donald R. Bohay, MD
Associate Professor
Department of Orthopaedic Surgery
Michigan State University
Orthopedic Associates of Michigan
Grand Rapids, Michigan

Michel Bonnin, MD
Department of Orthopaedic Surgery
Centre Orthopédique Santy
Lyon, France

Michael E. Brage, MD
Assistant Professor of Clinical Orthopedics
Director, Foot and Ankle Services
Department of Orthopaedic Surgery
University of California, San Diego
South County Orthopaedic Specialists
Laguna Woods, California

Lloyd C. Briggs, Jr., MD
Associate Clinical Professor
Department of Orthopaedic Surgery
Orthopaedic Institute of Ohio
Lima, Ohio

Matteo Cadossi, MD
PhD Student
Department of Human Anatomy and Pathophysiology of Musculoskeletal System
2nd Orthopaedic Department
Istituto Orthopedico Rizzoli
University of Bologna
Bologna, Italy

John T. Campbell, MD
Institute for Foot and Ankle Reconstruction at Mercy Medical Center
Baltimore, Maryland

Fabio Catani, MD
Professor of Orthopaedics
Department of Orthopaedic Surgery
Istituto Orthopedico Rizzoli
University of Bologna
Bologna, Italy

Wen Chao, MD
Department of Orthopaedic Surgery
PennCare—Pennsylvania Orthopaedic Foot and Ankle Surgeons
Philadelphia, Pennsylvania

Timothy Charlton, MD
Assistant Professor of Clinical Orthopaedics
Keck School of Medicine
University of Southern California
USC Orthopaedic Surgery Associates
Los Angeles, California

Christopher P. Chiodo, MD
Brigham Foot and Ankle Center at Faulkner Hospital
Boston, Massachusetts

Thomas O. Clanton, MD
Professor of Orthopaedic Surgery
The University of Texas Medical School at Houston
Director, Foot and Ankle Sports Medicine
The Steadman Clinic
Vail, Colorado

Michael P. Clare, MD
Director of Fellowship Education, Foot & Ankle Fellowship
Florida Orthopaedic Institute
Tampa, Florida

J. Chris Coetzee, MD, FRSCS
Minnesota Orthopedic Sports Medicine Institute
Eden Prairie, Minnesota

Bruce Cohen, MD
Department of Orthopedic Surgery
Carolina Medical Center
Charlotte, North Carolina

Jean-Alain Colombier, MD
Department of Orthopaedic Surgery
Clinique de L’Union
Saint Jean, France

Michael J. Coughlin, MD
Chief of Orthopaedics
St. Alphonsus Regional Medical Center
Clinical Professor of Surgery
Department of Orthopaedics
Oregon Health Sciences University
Boise, Idaho

Justin S. Cummins, MD, MS
Department of Orthopedic Surgery
SMDC Health System
Duluth, Minnesota

Richard J. deAsla, MD
Co-Director, Foot and Ankle Unit
Instructor
Department of Orthopaedic Surgery
Harvard Medical School
Boston, Massachusetts

Bryan D. Den Hartog, MD
Assistant Clinical Professor
Department of Orthopaedics
Sanford School of Medicine
Rapid City, South Dakota

Jonathan T. Deland, MD
Chief, Foot and Ankle Service
Associate Attending Orthopaedic Surgeon
Hospital for Special Surgery
Associate Professor
Department of Orthopaedic Surgery
Weill Cornell Medical College
New York, New York

James K. DeOrio, MD
Associate Professor
Division of Orthopedic Surgery
Department of Surgery
Duke University
Durham, North Carolina

Matthew J. DeOrio, MD
The Orthopedic Center
Huntsville, Alabama

Benedict F. DiGiovanni, MD
Associate Professor of Orthopaedics
University of Rochester Medical Center
Rochester, New York
Christopher W. DiGiovanni, MD
Director and Professor
Brown University Orthopaedic Residency Program
Chief, Foot and Ankle Service
Department of Orthopaedic Surgery
The Warren Alpert School of Medicine
Brown University
Rhode Island Hospital
Providence, Rhode Island

Brian Donley, MD
Director, Center for Foot and Ankle
Department of Orthopaedic Surgery
Cleveland Clinic
Cleveland, Ohio

Thomas Dreher, MD
Orthopaedic Department
University of Heidelberg
Heidelberg, Germany

Brad Dresher, MD
Department of Orthopaedics
Penrose St. Francis Medical Center
Colorado Springs, Colorado

Mark E. Easley, MD
Associate Professor of Orthopaedic Surgery
Co-Director, Foot and Ankle Fellowship
Duke University Medical Center
Durham, North Carolina

Patrick Ebeling, MD
Associate Clinical Instructor
Department of Orthopaedic Surgery
University of Minnesota
Burnsville, Minnesota

Andrew J. Elliott, MD
Assistant Professor
Department of Orthopaedic Surgery
Hospital for Special Surgery
New York, New York

Cesare Faldini, MD
Professor of Orthopaedics
Department of Human Anatomy and Pathophysiology of Musculoskeletal System
2nd Orthopaedic Department
Istituto Ortopedico Rizzoli
University of Bologna
Bologna, Italy

Nicholas A. Ferran, MBBS, MRCSEd
Specialist Registrar
Department of Trauma and Orthopaedics
Lincoln County Hospital
Lincolnshire, United Kingdom

Lamar L. Fleming, MD
Professor and Chairman
Department of Orthopaedics
Emory University School of Medicine
Atlanta, Georgia

Adolph S. Flemister, Jr., MD
Associate Professor
Department of Orthopaedics
University of Rochester
Rochester, New York

Austin T. Fragomen, MD
Limb Lengthening Specialist
Fellowship Director, Director of Education, and Director of Limb Lengthening and Deformity Service
Hospital for Special Surgery
New York, New York

Carol Frey, MD
Assistant Clinical Professor of Orthopaedic Surgery (Volunteer)
University of California, Los Angeles
Manhattan Beach, California

Delan Gaines, MD
Department of Sports Medicine
Southeastern Orthopedic Center
Savannah, Georgia

Richard E. Gellman, MD
Clinical Assistant Professor
Department of Orthopaedic Surgery
Oregon Health Sciences University
Summit Orthopaedics
Portland, Oregon

Sandro Giannini, MD
Professor of Orthopaedics
Department of Human Anatomy and Pathophysiology of Musculoskeletal System
2nd Orthopaedic Department
Istituto Ortopedico Rizzoli
University of Bologna
Bologna, Italy

Brian D. Giordano, MD
Department of Orthopaedics
University of Rochester
Rochester, New York

Jason P. Glover, DPM
Department of Foot and Ankle Surgery
Rutherford Hospital
Rutherfordton, North Carolina

John S. Gould, MD
Professor of Surgery/Orthopaedics
University of Alabama at Birmingham
Birmingham, Alabama

Gregory P. Guyton, MD
Department of Orthopedic Surgery
Union Memorial Hospital
Baltimore, Maryland

Steven L. Haddad, MD
Associate Professor of Clinical Orthopaedic Surgery
University of Chicago Pritzker School of Medicine
Section Head, Foot and Ankle Surgery
NorthShore University HealthCare Systems
Illinois Bone and Joint Institute, LLC
Glenview, Illinois

Professor
Director, Sigvard T. Hansen, Jr., MD Foot and Ankle Institute
Department of Orthopaedics and Sports Medicine
University of Washington
Seattle, Washington

Paul Hamilton, BMedSci, FRCS(Tr&Orth)
Senior Clinical Fellow
Department of Orthopaedics
Guy’s and St. Thomas’ NHS Foundation Trust
London, England

William G. Hamilton, MD
Clinical Professor
Department of Orthopedic Surgery
Columbia University College of Physicians and Surgeons
New York, New York

Thomas G. Harris, MD
Assistant Professor
Department of Orthopaedics
UCLA-Harbor Medical Center
Torrance, California

Paul J. Hecht, MD
Associate Professor
Department of Orthopaedic Surgery
Dartmouth Hitchcock Medical Center
Lebanon, New Hampshire

W. Bryce Henderson, BS, MD, FRCS
Chief of Orthopedics
Department of Orthopaedic Surgery
Red Deer Hospital, Central Alberta
Alberta, Canada

John E. Herzenberg, MD, FRCS
Director, International Center for Limb Lengthening
Rubin Institute for Advanced Orthopedics
Sinai Hospital of Baltimore
Baltimore, Maryland

Beat Hintermann, MD
Associate Professor of Medicine
Orthopaedic Clinic
University of Basel
Liestal, Switzerland

Stefan G. Hofstaetter, MD
Orthopaedic Senior Resident
Department of Orthopedics
Klinikum Wels-Grieskirchen
Wels, Austria

George B. Holmes, Jr., MD
Assistant Professor
Director, Section of Foot and Ankle
Rush University Medical Center
Westchester, Illinois

Jason M. Hurst, MD
Associate Partner
Joint Implant Surgeons
New Albany, Ohio

James J. Hutson, Jr., MD
Associate Clinical Professor
Department of Orthopedic Surgery
Miller School of Medicine
University of Miami
Miami, Florida

Christopher F. Hyer, DPM, FACFAS
Co-Director, Foot and Ankle Fellowship
Orthopedic Foot & Ankle Center
Westerville, Ohio
Clifford L. Jeng, MD
Institute for Foot and Ankle Reconstruction
Mercy Medical Center
Baltimore, Maryland

Shine John, DPM, AACFAS
Private Practitioner
Foot Specialists
Georgetown, Texas

Catherine E. Johnson, MD
Department of Orthopaedic Surgery
Massachusetts General Hospital
Watertown, Massachusetts

Jeffrey E. Johnson, MD
Associate Professor
Chief, Foot and Ankle Service
Department of Orthopaedic Surgery
Barnes-Jewish Hospital at Washington University Medical Center
St. Louis, Missouri

Kevin L. Kirk, DO
Chief
Orthopedic Surgery Service
San Antonio Military Medical Center
Houston, Texas

Alex J. Kline, MD
Department of Orthopaedic Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Markus Knupp, MD
Department of Orthopaedics
Kantonsspital Liestal
Liestal, Switzerland

Sameh A. Labib, MD
Assistant Professor of Orthopedic Surgery
Director of Foot and Ankle Service
Emory University
Atlanta, Georgia

Bradley M. Lamm, DPM, FACFAS
Head, Foot and Ankle Surgery
International Center for Limb Lengthening
Rubin Institute for Advanced Orthopedics
Sinai Hospital of Baltimore
Baltimore, Maryland

Geoffrey S. Landis, DO
Tucson Orthopaedic Institute Oro Valley
Oro Valley, Arizona

Johnny T. C. Lau, MD, MSc, FRCS(C)
Assistant Professor of Surgery
University Health Network – Toronto Western Division
Toronto, Ontario, Canada

Ian L. D. Le, MD
Department of Orthopaedic Surgery
Duke University Medical Center
Durham, North Carolina

Alberto Leardini, DPhil
Movement Analysis Laboratory
Istituto Orthopedico Rizzoli
Bologna, Italy

Simon Lee, MD
Assistant Professor
Department of Orthopaedic Surgery
Rush University Medical Center
Westchester, Illinois

Johnny Lin, MD
Assistant Professor
Department of Orthopaedic Surgery
Rush University Medical Center
Westchester, Illinois

Sheldon Lin, MD
Associate Professor
Department of Orthopaedics
University of Medicine and Dentistry of New Jersey
NJ Medical School
Newark, New Jersey

Umile Giuseppe Longo, MD
Consultant
Department of Orthopaedic and Trauma Surgery
Campus Biomedico University
Rome, Italy

Deianira Luciani, MD
PhD Student
Department of Human Anatomy and Pathophysiology of Musculoskeletal System
2nd Orthopaedic Department
Istituto Orthopedico Rizzoli
University of Bologna
Bologna, Italy

Nicola Maffulli, MD, MS, PhD, FRCS(Orth.)
Professor of Orthopaedic and Trauma Surgery
Centre for Sports and Exercise Medicine
Barts and The London School of Medicine and Dentistry
London, England

Ansar Mahmood, MD

When a surgeon contemplates performing a procedure, there are three major questions to consider: Why is the surgery being done? When in the course of a disease process should it be performed? And, finally, what are the technical steps involved? The purpose of this text is to describe in a detailed, step-by-step manner the “how to do it” of the vast majority of orthopaedic procedures. The “why” and “when” are covered in outline form at the beginning of each procedure. However, it is assumed that the surgeon understands the basics of “why” and “when,” and has made the definitive decision to undertake a specific case. This text is designed to review and make clear the detailed steps of the anticipated operation.

Operative Techniques in Orthopaedic Surgery differs from other books because it is mainly visual. Each procedure is described in a systematic way that makes liberal use of focused, original artwork. It is hoped that the surgeon will be able to visualize each significant step of a procedure as it unfolds during a case.

The text is divided into nine major topics: Adult Reconstruction; Foot and Ankle; Hand, Wrist, and Forearm; Oncology; Pediatrics; Shoulder and Elbow; Sports Medicine; Spine; and Pelvis and Lower Extremity Trauma. Each chapter has been edited by a specialist who has specific expertise and experience in the discipline. It has taken a tremendous amount of work for each editor to enlist talented authors for each procedure and then review the final work. It has been very stimulating to work with all of these wonderful and talented people, and I am honored to have taken part in this rewarding experience.

Finally, I would like to thank everyone who has contributed to the development of this book. Specifically, Grace Caputo at Dovetail Content Solutions, and Dave Murphy and Eileen Wolfberg at Lippincott Williams & Wilkins, who have been very helpful and generous with their input. Special thanks, as well, goes to Bob Hurley at LWW, who has adeptly guided this textbook from original concept to publication.

SWW
January 1, 2010
I would like to acknowledge my wife, Mary, and my children Erin, Colleen, John, and Kelly, who tolerate all the orthopaedic “homework” required to write and teach orthopaedics.

—JMF

I greatly acknowledge the never-ending hard work, dedication, and enthusiasm of Ms. Kristen Kellar-Graney, who has been my right-hand woman for over 12 years.

—MMM

All book projects are a challenge and I certainly could not get as involved with them as I am without a lot of help. To my partners (especially David), my PAs (Jen and Jerry), the residents and fellows, and everyone I have had the pleasure to teach and learn alongside. Thank you!

—MDM

With appreciation to my great mentor, Richard Rothman, MD, PhD, the most amazing human and scholar I have known.

—JP

I acknowledge my mentors and colleagues, Mark Myerson, Lew Schon, Robert Anderson, Hodges Davis, Jim Nunley, and Jim DeOrio, whose tireless commitment to academic orthopaedic surgery continues to inspire me, and the tremendous contributions of the authors who shared their expertise to make this textbook possible.

—MEE
The editors and the publisher would like to thank the resident reviewers who participated in the reviews of the manuscript and page proofs. Their detailed review and analysis was invaluable in helping to make certain this text meets the needs of residents today and in the future.

Daniel Galat, MD
Dr. Galat is a graduate of Ohio State University College of Medicine and the Mayo Clinic Department of Orthopedic Surgery residency program. He is currently serving at Tenwek Hospital in Kenya as an orthopedic surgeon.

Chapter 54
Chronic Exertional Compartment Syndrome 443

Chapter 55
Common Peroneal and Lateral Femoral Cutaneous Nerve Injuries 453
DEFINITION

- The shoulder is a spheroidal multiaxial joint stabilized not only by its bony anatomy but also by the surrounding muscles and capsular structures.
- Arthroscopy is the process of visualization and examination of a joint using a fiberoptic instrument. All shoulder surgeons must be proficient in diagnostic arthroscopy of the shoulder.

ANATOMY

- The glenohumeral joint consists of the glenoid fossa of the scapula that articulates with the head of the humerus.
- The labrum is a “bumper” of fibrocartilaginous tissue around the rim of the glenoid that acts to deepen and enlarge the glenoid fossa and increase glenohumeral stability. The biceps tendon is anchored at the superior labrum and acts as a humeral head depressor and also aids in glenohumeral stability.
- The static stabilizers of the shoulder include the joint capsule and the glenohumeral ligaments—superior, middle, and inferior glenohumeral ligaments. These will be discussed in greater detail in subsequent chapters.
- The dynamic stabilizers of the shoulder are the rotator cuff muscles—supraspinatus, infraspinatus, subscapularis, and teres minor.
- The scapular stabilizers—rhomboids, levator scapulae, trapezius, and serratus anterior—also contribute to dynamic stability of the shoulder.

PATHOGENESIS

- Shoulder injuries can occur secondary to trauma, microtrauma, or overuse injuries and can be activity- and age-dependent.
- Most patients under age 40 will have symptoms typical of overuse or instability, whereas patients over age 40 present more commonly with rotator cuff, impingement, inflammatory, or degenerative joint disease types of symptoms.

NATURAL HISTORY

- Shoulder injuries can be painful and lead to shoulder dysfunction.
- Recurrent shoulder instability decreases with age.\(^1\)
- The frequency of rotator cuff tears increases with age.\(^2\)
- If shoulder pathology is left unaddressed, pain, motion loss, degenerative changes, loss of function, and inability to participate in sports or work can occur.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most important part of the physical examination consists of taking an accurate history from the patient.
- Was it a traumatic, nontraumatic, or overuse injury?
- When and how did the injury occur?
- Is the patient’s complaint of pain, loss of motion, weakness, or inability to perform sports, activities of daily living, or work?
- Is there pain at rest, only with activity, or while sleeping?
- Are there any neurologic symptoms?
- Basic physical examination methods are summarized below. More specific examinations for different diagnoses will be described in other chapters in this section.
- Observation of patient with shoulder pain from the front, back, and side
  - Identify any muscle atrophy and asymmetry of muscles, shoulder height, or scapular position.
- Palpation of different parts of shoulder—sternoclavicular joint, acromioclavicular joint, greater tuberosity and rotator cuff, glenohumeral joint, biceps tendon, trapezium—to localize any areas of point tenderness, which may aid in differential diagnosis.
- Passive and active range of motion—forward flexion, abduction, adduction, internal and external rotation
  - Loss of range of motion may indicate adhesive capsulitis, rotator cuff pathology (tendinitis or rotator cuff tear), or degenerative changes.
- Resistive testing of deltoid, supraspinatus, infraspinatus, and subscapularis
  - Weakness of any muscles may indicate nerve injury, torn muscle or tendon, or weakness secondary to pain.
- Rotator cuff and scapular stabilizers: Look for atrophy, scapular winging, weakness with strength testing, and painful range of motion.
- Provocative tests for rotator cuff tear include drop arm sign and lift off or belly press for subscapularis.
- Impingement tests include the Neer and Hawkins tests.
- Labrum: Catching, clicking, popping may indicate a labral tear; check for instability with provocative tests (load shift, apprehension test or crank test, relocation, O’Brien’s).
- Multidirectional instability: Look for increased laxity inferiorly and in one other direction.
  - The sulcus sign demonstrates inferior laxity.
  - Check for the ability to voluntarily subluxate or dislocate the humeral head.
- Acromioclavicular joint: localized tenderness over the acromioclavicular joint and pain with cross-chest adduction and O’Brien’s testing

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs are used to assess different aspects of the shoulder joint.
- Basic radiographs should consist of anteroposterior, axillary, and outlet views.
- Special views may be obtained depending on shoulder pathology and will be discussed in subsequent chapters.
Magnetic resonance imaging (MRI) and MRI arthograms are also commonly obtained to aid in diagnosis because they are highly sensitive and specific in diagnosing many shoulder injuries.

**DIFFERENTIAL DIAGNOSIS**
- Impingement (internal or external)
- Rotator cuff tear
- Adhesive capsulitis
- Acromioclavicular joint injury or arthritis
- Labral tear
- Instability
- Biceps tendon pathology
- Degenerative arthritis
- Scapulothoracic dysfunction
- Cervical or neurologic
- Infection

**NONOPERATIVE MANAGEMENT**
- Nonoperative management for many different diagnoses may first consist of rest, nonsteroidal anti-inflammatories, physical therapy, and diagnostic and therapeutic injections.

**SURGICAL MANAGEMENT**
- A patient who has failed to respond to nonoperative management and continues to have symptoms consistent with his or her diagnosis is a candidate for shoulder arthroscopy.

**Preoperative Planning**
- Patient history and imaging studies are reviewed.
- The surgeon should have a good understanding of what pathology to expect at the time of arthroscopy to ensure that all appropriate equipment and instruments are available.
  - Patient positioning aids (arm holders, weights, beanbag, axillary roll)
  - Arthroscopic pumps or irrigation system
  - Video monitor, 30- and 70-degree arthroscopes
  - Arthroscopic cannulas
  - Shavers, burrs, suture anchors, arthroscopic instruments (probe, grasper, scissors, basket)
  - An examination under anesthesia is performed to assess range of motion and stability.

**Positioning**
- Shoulder arthroscopy may be performed with the patient in either a beach-chair position or the lateral decubitus position (FIG 1).
- The beach-chair position requires a specially designed operating table attachment that ensures that the surgeon has adequate exposure to the patient’s posterior shoulder and the patient’s head is well supported.
  - The advantage of this position is that the shoulder can be freely manipulated throughout the procedure.
  - Commercially available arm holders can also be used to allow glenohumeral distraction and positioning without the need for an assistant.
  - When using the lateral decubitus position (FIG 1B), the patient must be properly padded and the body supported with a beanbag, axillary roll, and pillows.

The operative extremity is placed in a commercially available arm holder in approximately 70 degrees of abduction and 15 to 20 degrees of forward flexion, with 10 pounds of weight for traction. This allows for distraction of the glenohumeral joint and offers excellent visualization.

**Approach**
- The operating room should be set up to allow the surgeon easy access to the entire shoulder and permit optimal visualization of the video monitors and arthroscopic equipment.
  - The typical operating room setup is shown in FIG 2.
  - The entire shoulder, arm, forearm, and hand and the exposed portion of the patient’s hemithorax should be steriley prepared after isolation with a clear U-drape. This will aid in keeping the patient dry in case fluid leaks under the surgical drapes.

**FIG 1**
- **A.** Patient in beach-chair position with standard draping for right shoulder arthroscopy.
- **B.** Patient in right lateral decubitus position with shoulder distraction apparatus to abduct and distract the left upper extremity.

**FIG 2**
- Operating room setup to allow optimal visualization of monitor and arthroscopic equipment.
Chapter 1  SHOULDER ARTHROSCOPY: THE BASICS 9

TECHNIQUES

SETUP AND PORTAL PLACEMENT

- Once the patient is prepared and draped, the bony surface anatomy should be outlined with a surgical marking pen. This includes the clavicle, borders of the acromion (anteriorly, posteriorly, and laterally), the spine of the scapula, the acromioclavicular joint, and the coracoid (TECH FIG 1).

- The posterior portal is created first.
  - A 5-mm skin incision is made using a number 11 scalpel.
  - All shoulder arthroscopy incisions should penetrate only the skin and no deeper to avoid injury to neurovascular structures and possible damage to articular surfaces.
  - The arthroscope sheath and blunt obturator are then inserted into the glenohumeral joint (TECH FIG 2).
  - The trocar should be directed toward the coracoid. One hand can be used to stabilize the shoulder and the index finger used to palpate the coracoid tip.
  - The obturator should be directed just medial to the humeral head and into the space between the head and glenoid. There should be a “pop” once the capsule is penetrated and the cannula is within the glenohumeral joint.
  - Some surgeons prefer first to inject saline with a spinal needle into the glenohumeral joint. This expands the joint and allows a bigger target as well as, with fluid return, confirms that the arthroscope is in the proper place.
  - The irrigation system and pump is turned on and the humeral head, glenoid, and biceps tendon are identified for quick orientation.
  - A brief inspection of the glenohumeral joint can be performed to determine whether modification of the subsequent portals may be required.

- All expected portal sites should next be marked. For a basic diagnostic arthroscopy these should include a posterior, anterior, and if necessary lateral portal. Accessory portal locations required for specific procedures will be discussed in subsequent chapters.
  - Posterior portal: 2 to 3 cm inferior and 1 cm medial to the posterolateral border of the acromion. It is usually located in the “soft spot” of the posterior shoulder that can be palpated between the posterior rotator cuff muscles (infraspinatus and teres minor).
  - Anterior portal: This portal is marked just lateral to the tip of the coracoid process and inferior to the anterolateral acromial border. Care must be taken to ensure that all anterior portals are lateral to the coracoid to avoid damage to the neurovascular structures located medial to the coracoid.
  - Lateral portal: This portal is marked 3 to 5 cm lateral to the lateral margin of the acromial border. The location of this portal may change based on the intra-articular anatomy.
  - Before starting the arthroscopic procedure, the surgeon ensures that all arthroscopic equipment (arthroscope, monitor, pump) is properly functioning.

TECH FIG 1 • Right shoulder with preoperative markings identifying the acromion, clavicle, and expected portal sites.

TECH FIG 2 • Arthroscope insertion. The trocar and arthroscopic cannula are directed toward the coracoid process. It enters the glenohumeral joint just lateral to the posterior glenoid labrum and approximately in the middle of the glenoid from superior to inferior. The surgeon’s index finger is on the tip of the coracoid to help direct the trocar into the joint.
ESTABLISHING THE ANTERIOR PORTAL

- The anterior portal is next created. Depending on the intra-articular shoulder pathology to be addressed, a modified anterior portal may be needed; this is discussed in other chapters.
- For most standard arthroscopic procedures, the anterior portal may be created using either an inside-out or an outside-in technique.

**Inside-Out Technique**

- The arthroscope is placed within the rotator interval just inferior to the biceps tendon and held firmly against the anterior capsule. The camera is then removed while holding the cannula in position.
- A switching stick or Wissinger rod (a long metal rod that fits within the arthroscopic sheath) is inserted into the cannula and used to penetrate the anterior capsule and tent the skin.
- A small skin incision is made over the end of the switching stick.
- A cannula may then be passed over the switching stick and into the glenohumeral joint.

**Outside-In Technique**

- A spinal needle is inserted at the expected site of the anterior portal and into the joint (TECH FIG 3).

**TECH FIG 3** - Spinal needle inserted in rotator interval to establish correct placement of anterior superior portal. The humeral head (H) and the long head of the biceps tendon (B) are clearly identified.

**DIAGNOSTIC ARTHROSCOPY**

**Arthroscope in the Posterior Portal**

- Diagnostic arthroscopy of the shoulder begins with the arthroscope in the posterior portal and a probe through the anterior portal. From this position, the following structures should be visualized and probed:
  - Articular surfaces of the humeral head and glenoid
    - The cartilage surface is evaluated, noting any chondral damage.
    - The glenoid cartilage may have a normal “thinned-out” appearance at its center.
  - Occasionally, the demarcation of the two ossific centers of the glenoid may be identified as a thin line on the chondral surface.
  - Subscapularis tendon and rotator interval
    - The integrity of the superior tendinous edge of the subscapularis and its attachment to the lesser tuberosity is evaluated (TECH FIG 4A).
    - The tissue quality and laxity of the rotator interval (the capsular tissue between the anterior edge of the supraspinatus and the superior edge of the subscapularis) is noted.
  - Superior and middle glenohumeral ligaments
    - The superior ligament is evaluated as it crosses between the subscapularis and biceps tendon and the middle ligament as it crosses the subscapularis tendon (TECH FIG 4B).
  - Variants may include a Buford complex (cord-like middle glenohumeral ligament) or even absence of the ligament altogether.
  - Superior labrum and biceps tendon
    - The biceps tendon is evaluated on both sides, using a probe to pull it into the joint to evaluate for hidden synovitis or fraying that exists as it leaves the joint and enters the bicipital groove (TECH FIG 4C).
  - Rotator cuff
    - The tendons of the rotator cuff are evaluated with the arthroscope looking superiorly. The rotator cuff tendon attachment to the humeral head should be smooth, without any fraying (TECH FIG 4D).
    - As the arthroscope is moved posteriorinferiorly around the humeral head, the normal “bare spot” on the humeral head is easily identified by the lack of articular cartilage and the presence of nutrient foramen in the bone (TECH FIG 4E).
  - Inferior capsule and recess
    - The inferior capsular pouch and the capsular attachment to the humeral head are assessed (TECH FIG 4F).
    - Occasionally a humeral avulsion of the inferior glenohumeral ligament may occur here with or without a fragment of bone.
Chapter 1  SHOULDER ARTHROSCOPY: THE BASICS

TECH FIG 4 • A. Left shoulder in lateral decubitus position with anterior superior and anterior inferior portals established. The biceps tendon (B) is between the two cannulas. The humeral head (H), glenoid (G), and superior edge of the subscapularis (S) are identified. B. Left shoulder in beach-chair position, with subscapularis (S), biceps tendon (B), and middle glenohumeral ligament (M) identified. The anterosuperior labrum is highly variable and in this case presents as a sublabral hole (arrow). C. The long head of the biceps can be pulled into the joint to inspect for synovitis (arrows), as shown in this shoulder. D. The anterior edge of the suprapinatus and the normal rotator cuff insertion are depicted in this image. E. As the arthroscope is swept posteriorly along the rotator cuff, the bare area of the humeral head is identified. This is a normal area devoid of articular cartilage. The transition between the posterior rotator cuff and the inferior capsule is identified (arrow). F. The inferior capsular pouch is seen attaching to the humerus. This is a common area to find loose bodies as they tend to fall to the most dependent aspect of the joint (in the beach-chair position). G. The inferior glenoid labrum can be visualized as the arthroscope is redirected superiorly from the axillary pouch. H,I. The anterior labral attachment is inspected. H. The labrum and capsular attachment are normal. I. There is a disruption in the attachment of the anteroinferior labrum (Bankart lesion). J. The superior labral attachment is probed.
As the arthroscope is directed superiorly, the inferior labral attachment can be examined (TECH FIG 4G).

Anterior band of the inferior glenohumeral ligament
This is the primary static stabilizer to anterior glenohumeral translation.

The anteroinferior labrum should be tightly attached to the glenoid (TECH FIG 4H). Detachment in this area is commonly referred to as a Bankart or Perthes lesion (TECH FIG 4I) and will be discussed in greater detail in Chapter SM-2.

Visualization of this ligament is facilitated when the ligaments and capsular tissues are loose and the arthroscope may easily pass into the anterior recess between the humeral head and glenoid. This is known as a “drive-through” sign and may represent multidirectional laxity.

Biceps anchor
The superior labral attachment to the glenoid is probed to evaluate for a superior labral anterior to posterior (SLAP) lesion.3

Typically the superior labrum is well attached to the superior glenoid (TECH FIG 4J).

Normal variants such as a meniscoid superior labrum and variations of the biceps tendon (bifid tendon) are not uncommon. They must be differentiated from pathoanatomy that requires repair.

**Arthroscope in the Anterior Portal**
- The arthroscope is removed while keeping the sheath in the joint posteriorly. It is placed in the anterior cannula to allow evaluation of the posterior joint and to assess the rest of the joint from another viewpoint.

**SUBACROMIAL ARTHROSCOPY (BURSCOSCOPY)**
- Once the diagnostic glenohumeral arthroscopy is completed, the sheath and obturator are then directed into the subacromial space.
- This is done by placing the obturator tip just beneath the posterior acromion and then inserting it parallel to the acromion.
- If the arthroscope is inserted properly into the subacromial space anterior to the posterior bursal curtain, then the distended bursal space should allow for visualization of the subacromial structures.3
- At the surgeon’s preference, a lateral portal may be created at this time.
- The inferior aspect of the acromion is evaluated and the coracoacromial ligament is identified.
- The lateral and anterior aspects of the acromion are assessed.
- The anterior acromial spur is evaluated if present.
- The arthroscope is oriented to look downward at the greater tuberosity and attachment of the rotator cuff.

- The posterior labrum should be smooth and tightly attached to the glenoid (TECH FIG 5).
- The scope is angled upward to assess posterior capsular attachment to the humeral head. If detached, this represents a reverse humeral avulsion of the glenohumeral ligament.
- Subscapularis and biceps tendon
  - The subscapularis recess and subscapularis attachment to the humeral head can be evaluated.
  - Loose bodies are occasionally found within the subscapularis recess.
  - Integrity and stability of the groove and the synovium of the biceps tendon are evaluated.
PEARLS AND PITFALLS

| Indications | The surgeon should have a clear understanding of patient history, physical examination, imaging studies, and pathology to be addressed. |
| Positioning | Beach-chair or lateral decubitus position is used. The surgeon should ensure that the appropriate equipment is available in the operating room. |
| Portal placement | The surgeon should have a full understanding of pertinent anatomy. Improper portal placement will make visualization and arthroscopic débridement and repair difficult. |
| Equipment | The surgeon must make sure that all necessary equipment and instruments are available, including suture anchors for labral repair or rotator cuff procedures, multiple-size cannulas, sutures and passing instruments, shavers and burrs, and thermal or electrocautery. |
| Approach | It is important to have a systematic, stepwise approach to diagnostic arthroscopy so that all structures are adequately visualized and no pathology is missed. |

POSTOPERATIVE CARE

- The patient is placed in a sling for comfort. Allowable range of motion and exercises are tailored to the specific procedure performed and will be discussed in detail in the following chapters.
- Cryotherapy (a commercial ice unit) may be used.

OUTCOMES

- Shoulder arthroscopy is a safe and effective procedure. It allows for complete visualization of the glenohumeral joint and subacromial space and treatment of identified pathology.
- Outcome data for specific procedures performed are discussed in the following chapters.

COMPLICATIONS

- Failure to address all pathology with thorough diagnostic examination
- Infection
- Loss of motion or adhesive capsulitis

REFERENCES

DEFINITION
- Glenohumeral stability depends on static and dynamic restraints to ensure stable yet unconstrained range of motion.
- Laxity is a physiologic term used to describe the passive translation of the humeral head on or over the glenoid.
- Instability is a pathologic state characterized by abnormal translation of the humeral head on or over the glenoid, leading to frank dislocation, functional impairments, or pain.
- The most common direction of glenohumeral instability is anteroinferior.
- Anterior instability may be traumatic (occurring with the arm in abduction and external rotation), acquired (subtle instability associated with repeated microtrauma), or atraumatic (multidirectional with underlying anatomic contributions).

ANATOMY
- The normal glenoid is broader inferiorly than superiorly (pear-shaped).
- The articulating surface of the humeral head is about three times the size of the corresponding glenoid cavity.
- Static and dynamic stability must be provided by a complex interaction between the capsuloligamentous structures, the rotator cuff, the scapular stabilizers, and the biceps muscle.
- The shallow bony glenoid is deepened by thicker articular cartilage on the periphery and the presence of the ringlike labrum.
- The fibrocartilaginous labrum increases the depth of the socket and prevents the head from rolling anteriorly over the glenoid. The superior labrum provides an attachment for the biceps, whereas the inferior labrum serves as an attachment for the glenohumeral ligaments.
- The capsule and ligaments are intimately related and different geographic areas contribute to stability based on the anatomic position of the arm.
- The inferior glenohumeral ligament complex is the primary static restraint against instability from abduction angles of 45 to 90 degrees. The anterior band is the most important static restraint against anterior instability in the most common position of injury, the abducted and externally rotated arm (FIG 1).
- The superior and middle glenohumeral ligaments limit inferior translation and anteroposterior translation with the arm in abduction.
- The rotator cuff muscles and the long head of the biceps brachii provide critical dynamic stability by increasing joint compression.
- Less important contributors to joint stability include negative intra-articular joint pressure, articular version, and adhesion-cohesion forces.

PATHOGENESIS
- Trauma, especially athletic trauma, plays a significant role in recurrent anterior instability.
- Overhead athletes can present with more subtle instability.
- Repetitive microtrauma contributes to the development of pathologic subluxation.
- Injury may result in subluxation and dislocation with spontaneous reduction or dislocation requiring reduction maneuvers.
- Traumatic anterior instability is most common in the young, athletic population.
- In the 21- to 30-year-old age group the male/female incidence was reported as 9:1.
- The Bankart lesion (detachment of the anterior inferior labrum and capsule) is considered the fundamental pathoanatomic lesion associated with anteroinferior instability. It may be present in about 90% of all traumatic glenohumeral dislocations (FIG 2).
- Recurrent dislocations lead to plastic deformation of the middle and inferior glenohumeral ligaments, contributing to laxity in the “sling” that is designed to restrict translation of the humeral head in abduction.
- Bone injuries to the humerus (such as the Hill-Sachs lesion) and the glenoid (bony Bankart or glenoid erosion) are known to contribute to increased glenohumeral translation, resulting in recurrent instability.
- Extensive soft tissue damage is rare but can include the humeral avulsion of the glenohumeral ligaments or a capsular tear. In addition, the injured labral tissue may heal medially on the glenoid neck (the so-called anterior labroligamentous periosteal sleeve avulsion [ALPSA lesion]) leading to insufficiency of the inferior glenohumeral ligament and labral complex.
- In the older patient with a traumatic dislocation, rotator cuff pathology must be ruled out. A thorough strength examination coupled with appropriate use of soft tissue imaging should alert the examiner to concomitant rotator cuff pathology.
- Other soft tissue injuries (capsular tear and neurovascular injury) as well as glenoid and humeral head defects can occur in this age group.
from posterior to assess any muscular atrophy of the trapezius.

The physical examination should begin with inspection

There are five important questions in the history of instability:
- Did the initial instability episode require a reduction?
- What was the arm position for the first dislocation? The last dislocation?
- What was the disability after the initial incident?
- How many episodes of instability have occurred since the initial event? Were they dislocation or subluxation episodes?
- What was the magnitude of the trauma associated with the initial event? Have subsequent events required similar force, or have they occurred with less provocation?

The physical examination should begin with inspection from posterior to assess any muscular atrophy of the trapezius, supraspinatus, and infraspinatus and teres minor. Muscle atrophy may point out nerve injury.
- Generalized ligamentous laxity should be examined by testing a thumb hyperextension sign and elbow extension.
- Active and passive range of motion in all scapular planes should be recorded and compared with the contralateral shoulder.
- Strength testing should include all important shoulder musculature, with a focus on pain as limiting factor.
- The contralateral side is examined when doing the load and shift examination; positive findings indicate lax anterior stabilizers.
- It is critical to separate feelings of pain from instability relieved with Jobe relocation. A positive relocation maneuver may spotlight subtle instability.
- Axillary nerve function should be assessed by carefully testing motor function of the deltoid and examining sensory distribution.

A positive posterior jerk test with pain and or crepitus illicit with posterior translation of the humeral head over the glenoid rim indicates posteroinferior capsular or labral pathology.
- When examining for the sulcus sign, the clinician should compare the result with the contralateral side. Failure of external rotation to eliminate the sulcus sign may indicate multidirectional instability or global laxity.
- Provocative maneuvers should be employed to evaluate shoulder stability.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs
  - Standard AP views of the arm with the arm in slight internal rotation: may show greater tuberosity fracture
  - AP views of the glenohumeral joint
  - West Point axillary view: may be used to assess bony avulsions of the inferior glenohumeral ligament, bony Bankart lesions, or anteroinferior glenoid deficiency
  - Stryker notch view: may be used to examine and quantify a Hill-Sachs lesion
- Computed tomography
  - Bone defects are an important cause of failure for instability surgery.
  - Three-dimensional reconstructions have been especially useful to quantify bone loss.
- Indications
  - Instability episodes while asleep
  - Instability episodes with minimal trauma after a primary instability episode that required manual reduction
  - Instability episodes at low degrees of humeral abduction
  - Failure of any prior instability procedure
  - Apprehension on examination at low degrees of humeral abduction
  - Remarkable laxity on load and shift test
  - Any bony lesion on radiographic evaluation
  - When bony deficiencies are identified, operative approaches must be adjusted accordingly. Careful consideration must be given to open instability procedures with bony augmentation in cases of bone involvement (Table 1).
- Magnetic resonance imaging
  - Contrast enhancement improves the ability to detect labral injury, rotator cuff tears, and articular cartilage lesions.
It may identify humeral avulsion of the glenohumeral ligament lesions and capsular tears, allowing recognition of these infrequent but critical injuries (FIG 3C).

**DIFFERENTIAL DIAGNOSIS**
- Osseous lesions, including clavicle fractures, proximal humerus fractures, and scapular and glenoid fractures
- Soft tissue lesions, including deltoid contusions, acromioclavicular joint sprains, and rotator cuff injuries (more common in patients older than 40 years)
- Nerve lesions, including injuries to the axillary nerve, suprascapular nerve, and long thoracic nerve

**NONOPERATIVE MANAGEMENT**
- Nonoperative management has traditionally consisted of a period of immobilization followed by intensive physical therapy to improve proprioception and muscular balance around the shoulder girdle. A recent review noted that recommendations for positioning, length of immobilization, and outcomes are inconsistent at best.\(^3\)
- Recent work by Itoi\(^14\) suggested that immobilization in external rotation will reduce recurrence rates after magnetic resonance imaging demonstrates coaptation of the Bankart lesion with the arm in external rotation.\(^17\) This same author reported a clinical series comparing immobilization in internal rotation versus external rotation after primary dislocation. Immobilization in external rotation reduced the risk of recurrence by 46%.\(^15\)
- Failure of nonoperative management may be manifested in recurrent symptoms of instability (dislocations, subluxations, or pain) despite adequate nonoperative management and activity modification where appropriate.

**SURGICAL MANAGEMENT**
- The guiding basis for the described arthroscopic technique is that restoration of the normal glenoid labrum anatomy and retensioning of the inferior glenohumeral ligament can be accomplished in a manner that mirrors the open method (FIG 4).

**FIG 3** • A. AP radiograph showing defect in the humeral head. B. CT scan reconstruction showing erosion of the anteroinferior glenoid. C. MRI example of humeral avulsion of glenohumeral ligament lesion.

**FIG 4** • Illustration of a surgical reconstruction with a 180-degree arthroscopic repair with three inferior plication sutures, three anchors repairing the labrum, and a rotator interval closure.
In the senior author’s experience with traumatic anterior instability, a Bankart lesion will typically extend from the 2 o’clock to the 6 o’clock position. To restore anatomy appropriately, the surgeon should be able to instrument and place suture anchors at the inferior aspect of the joint in the 6 o’clock position.

Arthroscopic knots may be sliding, sliding-locking, or simple. Knot selection is less important than the ability to reproduce the desired knot security and tissue tension consistently.

Preoperative Planning
- The indications for arthroscopic stabilization include:
  - Primary anterior dislocation in young, high-demand patients
  - Recurrent, traumatic anterior instability without bone loss
  - Overhead athletes, especially throwing athletes, where preserving motion is important
- Contraindications to arthroscopic stabilization include a large Hill-Sachs lesion (the “engaging” Hill-Sachs) and bony deficiencies of the glenoid that represent more than 20% (the “inverted pear”) (FIG 5).
- Arthroscopic stabilization for collision athletes and patients with osseous Bankart lesions is controversial.
  - However, several recent reports describe favorable results with arthroscopic repair in these groups.3,5,21,22,31
  - The decision to do arthroscopic versus open repair continues to be debated as arthroscopic results are reported (see Table 1).34
- All pertinent radiographic studies should be reviewed to confirm prior hardware, expected soft tissue injuries, and potential bony injuries.
- An examination under anesthesia should confirm anteroinferior instability in the operative shoulder and verify range of motion. It is important to note the normal range of motion in the contralateral shoulder before final positioning.

Positioning
- Both the beach-chair position and the lateral decubitus position may be used for instability surgery. We prefer the lateral decubitus position to allow greater access to the inferior portions of the joint.
- For the lateral decubitus position the patient is stabilized with a beanbag in a 30-degree backward tilt to place the glenoid face parallel to the floor.

- A three-point distraction device that applies longitudinal and vertical traction allows distraction of the humerus.
- Typically 5 pounds of longitudinal traction is combined with 7 pounds of lateral traction or distraction.
- In most cases an interscalene block provides excellent operative and postoperative pain control.
- For the beach-chair position, this may be all that is required.
- For the lateral decubitus position, it is prudent to add general anesthesia for comfort.
- Preoperative antibiotics are administered before the skin incision (FIG 6).

Approach
- A standard posterior portal should be placed in the soft spot at midglenoid level, taking care to be just lateral to the glenoid.
- The blunt arthroscopic trocar and sheath are then inserted into the space between the glenoid rim and the humeral head.
- Using needle localization, the surgeon places the anterior portals. The anterosuperior portal should be as high as possible while staying just inferior to the biceps tendon.
- The anteroinferior portal should enter just above the superior border of the subscapularis.
- The needle used for portal placement should first be navigated throughout the joint to ensure that instrumentation with suture shuttling devices and anchor insertion equipment is feasible.
- The anterosuperior portal is instrumented with a 7.0-mm cannula and the anteroinferior portal is instrumented with an 8.25-mm cannula (FIG 7A–C).

![A. Hill-Sachs lesion on glenoid face. B. Hill-Sachs lesion engaged, with humeral head locked over anterior glenoid. C. Arthroscopic view (right shoulder) of inverted pear: camera anterosuperior, showing anterior glenoid bone loss.](FIG 5)

![Setup for the lateral decubitus position with arm traction device.](FIG 6)
Before beginning the surgical procedure, a thorough diagnostic arthroscopy is performed.

After diagnostic arthroscopy, the arthroscope is brought to the anterosuperior portal and another 8.25-mm cannula is placed in the posterior portal.

With the arthroscope in the anterosuperior portal, visualization of the inferior glenohumeral ligament and labrum is optimized.

A rolled blanket “bump” placed into the axilla provides further gentle distraction and improves exposure of the inferior aspect of the joint (FIG 7D).

---

**Arthroscopy and Glenoid Preparation**

- First, the labral and ligamentous complex must be released off the face of the glenoid.
- Care should be taken to maintain the tissue as one unit, using elevators to adequately release to at least the 6 o’clock position.
- When muscle fibers of the subscapularis are visible, the release is adequate (TECH FIG 1A).
- The glenoid neck must be prepared by either a burr or a shaver to decorticate down to bleeding bone. A meniscal rasp can be a helpful adjunct.
- The bone preparation must be as inferior as the soft tissue release on the glenoid.
- It is critical to begin the repair at the low 6 o’clock position in the capsule.
- Various techniques may be used to ensure that the initial shuttling suture can be placed inferior at the 6 o’clock position. Options include:
  - Arthroscope in anterosuperior portal (our preferred method): suture-passing instrument inserted through posterior cannula (TECH FIG 1B)
  - Arthroscope in anterosuperior portal: suture-passing instrument inserted through anteroinferior cannula (TECH FIG 1C,D)

---

**“Pinch and Tuck”**

- Capsular retensioning and labral repair may be accomplished by the “pinch and tuck” method (TECH FIG 2).
- Using a curved suture-passing device, the capsule is pierced 5 to 10 mm lateral to the labrum.
- The device exits the capsule and pierces the capsule again to re-enter at the lateral base of the labral complex and emerge at the articular margin.
- A monofilament suture is inserted to be used as a shuttle suture. The shuttling suture or device will eventually be used to shuttle the nonabsorbable suture housed in the anchor. Or it may be used to shuttle a nonabsorbable suture being used purely as a plication suture.
- With the introduction of newer ultrastrong suture, subsequent knot tying will combine capsular plication and labral repair.
- All shuttling should be done from the articular side of the labrum out to the soft tissue side and through a cannula.
TECH FIG 1 • Right shoulder. A. Elevator releasing labral and capsular tissue off face of glenoid. B. Pinch of capsular and ligamentous tissue with shuttling instrument coming from posterior portal to place at inferior aspect. C. Shuttling instrument brought through anteroinferior portal and taking tuck of inferior capsule. D. After piercing capsule the needle of the shuttling instrument pierces the labrum. E. Camera in posterior portal with suture passer in anteroinferior cannula. F. Camera in anterosuperior portal with suture passer in anteroinferior cannula.

TECH FIG 2 • Camera in anterosuperior portal with suture passer in posterior cannula.

Anchor Placement

- The initial suture anchor is placed inferiorly on the glenoid, close to the 6 o’clock position.
- Suture anchors should be placed on to the articular face of the glenoid to recreate the “bumper” effect of the normal labrum.
- It is critical to place anchors 5 to 10 mm cephalad to the shuttle suture to accomplish the “superior shift” portion of the procedure (TECH FIG 3A). Subsequent knot-tying will combine capsular re-tensioning and labral repair.
- If appropriate access for anchor placement cannot be gained from the anteroinferior portal, a percutaneous transsubscapular entry may be used.
- In this case, a stab incision is made just inferior to the anteroinferior portal.
- Using needle localization the surgeon confirms appropriate access, and a small trocar may be inserted to place the anchor onto the glenoid (TECH FIG 3B,C).
Capsular Plication

- The process of capsular plication and anchoring is repeated, moving in a superior direction to restore labral anatomy and reposition the inferior gleno-humeral ligament.
- Typically at least four anchors are used in the final construct.

- It may be necessary to return the arthroscope to the posterior portal for placement of the most cephalad anchor (2 o’clock position for the right shoulder) to avoid anterior instrument crowding. A 7.0-mm cannula may be reinserted in the anterosuperior portal for instrumentation. The final repair should re-establish normal positioning of the glenoid labrum over the glenoid rim and reposition the inferior gleno-humeral ligament (TECH FIG 4A,B).

ANCHOR FIRST

- The same general techniques and principles from the suture-first technique apply.
- An anchor is inserted onto the face of the glenoid in an appropriate location.
- Both limbs of the anchor suture are pulled out of a cannula for suture management.

- A tissue penetrator or suture-shuttling device is used to gather the inferior tissue and place a shuttle suture.
- The suture is grasped in the joint and pulled out the anterosuperior cannula.
- A standard suture-shuttle technique is used to pass the anchor suture.

ADDITIONAL ENHANCING TECHNIQUES

Traction Suture

- If access to the inferior capsule and labrum is difficult, a “traction suture” can be used.
- The initial stitch can be placed in the inferior capsule and then brought out the anterosuperior portal.
- Traction on this stitch may allow a more inferior grasp of tissue in the early stages of a repair.

Mattress Suture

- In addition to simple sutures, a mattress suture can be used to position the tissue on the glenoid face.
- For a mattress suture, the process of capsular plication with a suture-passing device and subsequent suture shuttling is repeated so that both limbs of the suture exit the tissue on the tissue side.

- As the arthroscopic knot is tied, a mattress stitch is created to enhance capsular plication and gather additional capsular tissue on the glenoid rim.
- This is particularly useful with a degenerative atrophic labrum or with poor-quality capsular tissue (TECH FIG 5).

Posterior Anchors

- Should the Bankart lesion extend posteriorly past the 6 o’clock point, posterior anchors may be required.
- A percutaneous technique for anchor insertion can be employed using needle localization and a trocar and anchor guide through a postero-inferior stab incision.
- Alternatively, a postero-inferior portal may be established using needle localization and gradually increasing dilators to place an additional cannula for posterior and inferior access.
Plication Stitches

- If the posterior labrum is intact but posterior laxity remains, plication stitches can be placed to better balance the anterior and posterior tension on the inferior glenohumeral ligament.
- Using the pinch-tuck technique, the capsule and ligament can be grasped and connected to the labrum (TECH FIG 7).

Closure of Rotator Interval

- When additional stability is required, the rotator interval can be closed.
- Current recommendations for rotator interval closure include greater than 1/2 sulcus sign, laxity with a posterior component, and a collision athlete.9
- A stitch is passed through a suture passer placed in the anterosuperior cannula through the superior border of the subscapularis or the middle glenohumeral ligament.
- The superior glenohumeral and coracohumeral complex is then pierced with a tissue penetrator to grasp the suture. The suture is then tied and cut with a guillotine knot cutter (TECH FIG 8).
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Patient selection</th>
</tr>
</thead>
</table>
| Major reported reasons for failure of arthroscopic stability procedures include:
| - Failure to appreciate and address excess capsular laxity
| - Failure to evaluate and address bone loss adequately

<table>
<thead>
<tr>
<th>Portal placement pearls</th>
</tr>
</thead>
</table>
| - The posterior portal should be placed so that the camera angle replicates the angle of the glenoid face.
| - The anterosuperior portal should be placed far enough from the anteroinferior portal to maintain a skin bridge and working room.
| - The anteroinferior portal should enter just above the subscapularis so instruments and cannula are not blocked by the subscapularis and may reach the inferior glenoid and pouch.

<table>
<thead>
<tr>
<th>Technical considerations</th>
</tr>
</thead>
</table>
| - The labrum and the inferior glenohumeral ligament complex must be adequately released to at least the 6 o’clock position. The surgeon should visualize muscle fibers of the subscapularis.
| - Soft tissues must be mobilized superiorly on the glenoid to re-establish tension of the inferior glenohumeral ligament complex and decrease inferior capsule space.
| - Suture anchors must be placed 1 to 2 mm on the articular surface to recreate the soft tissue “bumper.”
| - Adequate fixation requires at least four stabilization points.
| - Suture management must be consistent and simple. Sliding, sliding-locking, and simple knots are all acceptable, provided the surgeon can consistently replicate a solid repair.

POSTOPERATIVE CARE

- Goals of postoperative care include controlled mobilization to allow adequate soft tissue healing, adequate motion (external rotation), and successful return to activities.
- Postoperative protocols must respect the biologic repair process.
- Our postoperative protocol includes:
  - Immediate postoperative immobilization in an abduction orthosis
  - Codman exercises and pendulum exercises immediately with assistance
  - Active assisted range-of-motion exercises, including external rotation (0 to 30 degrees) and forward elevation (0 to 90 degrees), for 6 weeks
  - Weeks 6 to 12 include active assisted and active range of motion with the goal of establishing full range of motion.
  - Strengthening exercises begin only after full motion is restored.
  - Sports-specific exercises are begun at 16 to 20 weeks.
  - Final release to full activity is 20 to 24 weeks.

OUTCOMES

- Multiple recent studies using a suture anchor technique similar to the open method have documented clinical success, with recurrent instability rates of 4% to 10%. 5,8,10,18,34
- As arthroscopic techniques and equipment have evolved, the literature indicates decreasing rates of recurrence and results approaching open instability procedures.
- Careful patient selection remains critical for arthroscopic instability procedures and may vary with surgeon experience.

COMPLICATIONS

- The overall rate of recurrent instability from arthroscopic stabilization can safely be placed at 10% to 15%.
- Postoperative glenohumeral noise or squeaking can occur if arthroscopic knots are captured in the glenohumeral joint. This may require later débridement of the knots.
- Loss of external rotation from overtightening can occur.
- Rupture of the repair can occur with aggressive early activities or rehabilitation.
- Injury to the axillary nerve is possible with electrical or mechanical damage.

REFERENCES

DEFINITION
- Posterior shoulder instability results in pathologic glenohumeral translation ranging from mild subluxation to traumatic dislocation. Most patients with this pathologic entity report pain in provocative positions of the glenohumeral joint, a condition referred to as recurrent posterior subluxation.
- Posterior shoulder instability is much less common than anterior instability, representing about 5% to 10% of all patients with pathologic shoulder instability.\(^2,5,10\)
- A decision must be made regarding surgical treatment of this condition when an extended trial of conservative measures, such as physical therapy, has failed.

ANATOMY
- The important stabilizing structures of the glenohumeral joint are the articular surfaces and congruity of the humerus and glenoid, the labral capsule, the labral capsular structures, the labrum, the intra-articular portion of the biceps tendon, and the rotator cuff muscles.
- Pathologies of the posterior capsule and labral complex are believed to be the main contributors to posterior instability.
- With the arm forward-flexed to 90 degrees, the subscapularis provides significant stability against posterior translation, and as the arm is placed in neutral, the coracohumeral ligament resists this force. With internal rotation of the shoulder (follow-through phase of throwing), the posterior capsulolabral complex is the main restraint to posterior translation.\(^1\)
- Histologic evaluation of the posterior capsule shows it to be relatively thin and composed of only radial and circular fibers, with minimal cross-linking.

PATHOGENESIS
- Posterior instability can be the result of trauma in the form of a direct blow to the anterior shoulder or may occur as the result of indirect forces acting on the shoulder, causing the combined movements of shoulder flexion, adduction, and internal rotation.\(^13\)
- Electrocution and seizures are the most common causes of an indirect mechanism resulting in posterior dislocation.
- Patients with recurrent posterior subluxation may present with more vague symptoms, with pain being the chief complaint. Athletes may report that velocity with throwing is diminished, and a sharp pain may accompany the follow-through phase of throwing.
- Other associated injuries such as superior labrum anterior posterior (SLAP) lesions, rotator cuff tears, reverse Hill-Sachs defects, and chondral injuries may be present and contribute to the pathology.\(^4\)

NATURAL HISTORY
- Patients with a history of a chronically locked posterior dislocation are at increased risk for the development of chondral injury and subsequent degenerative arthritis.\(^6\)
- Static posterior subluxations of the humeral head have been correlated with the presence of arthritis in young adults whose instability was left untreated.\(^14\)
- No long-term studies on the arthroscopic treatment of shoulder instability have documented a reduction in the development of osteoarthritis.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A thorough history is obtained, documenting whether a dislocation has occurred (as well as the need for closed reduction) or if the primary symptoms are pain.
- The circumstances regarding pain are documented, namely onset (provocations), severity, ability to participate in sports, and whether symptoms are present at rest.
- Any response to conservative treatment (ie, physical therapy, rest, anti-inflammatory medication) should be noted.
- As with the examination of any joint, the shoulder is palpated to elicit tenderness and range of motion is documented. Any restriction in motion should be compared to the contralateral extremity, and differences between active and passive motion may indicate pain or capsular contracture.
- Impingement signs are tested to determine whether any associated rotator cuff tendinitis is present.
- Other examinations for posterior instability are:
  - Strength testing. Weakness may be the result of deconditioning or may indicate underlying rotator cuff or deltoid pathology.
  - Load and shift test. The degree of pathologic subluxation is assessed, as well as any apprehension or pain experienced by the patient during provocative testing.
  - Jerk test. A positive jerk test indicates pathologic posterior subluxation.
  - Kim test. A positive Kim test suggests a posteroinferior labral tear or subluxation.
  - Circumduction test. A positive test result is highly suspicious of posterior subluxation or dislocation.
  - Sulcus sign evaluation. A positive sulcus sign suggests multidirectional instability.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs, including a glenohumeral anteroposterior view, scapular Y view, axillary lateral view, and supraspinatus outlet view, should be obtained to rule out associated injuries, bone defects (either humeral or glenoid), or degenerative changes (FIG 1A).
- Magnetic resonance (MR) arthrography is currently the best method for imaging the posterior capsulolabral structures.
- Findings on MR suggestive of posterior instability are posterior humeral head translation, posterior labral injury, posterior labrocapsular avulsion, humeral avulsion of the posterior band of the inferior glenohumeral ligament, posterior glenoid bone defects, and anterior humeral head bone defects (FIG 1B).
Differential Diagnosis

- Posterior shoulder dislocation (may be locked)
- Recurrent posterior subluxation
- Multidirectional instability
- Internal impingement
- SLAP tear
- Rotator cuff tear
- Acromioclavicular joint injury
- Fracture (e.g., glenoid, greater tuberosity)

Nonoperative Management

- An extended period of nonoperative management is warranted in most cases of posterior shoulder instability.
- Nonoperative therapy constitutes physical therapy to regain a full and symmetric shoulder range of motion, with later emphasis placed on strengthening the rotator cuff and scapular stabilizing muscles.
- The premise of a conditioning program is to enable the dynamic stabilizers of the shoulder to compensate for the deficient static stabilizers (e.g., capsule, labrum).
- Once full motion and strength are achieved, return to sport is gradually introduced.

Surgical Management

- Surgical management of posterior instability is considered when an exhaustive rehabilitation program has failed to alleviate disabling posterior subluxation, or when instability is the result of a macrotraumatic event.

Preoperative Planning

- All imaging studies are again reviewed and the pathology is determined.
- Any bone deficiencies, loose bodies, and concomitant rotator cuff and SLAP tears should be evaluated and treatment determined before arrival in the operating room.
- An examination under anesthesia is performed before positioning to confirm the diagnosis. This examination should consist of sulcus test, load and shift test, and manual circumduction test or jerk test.

Positioning

- We prefer lateral decubitus positioning because this offers greater exposure than the beach-chair position for evaluating the posterior labrum and capsule.
- An inflatable beanbag and kidney rests hold the patient in the lateral position.
- Foam cushions are used to pad the axilla and all bony prominences, including the fibular head (protection of the peroneal nerve).
- The operative extremity is placed in 10 pounds of traction in 45 degrees of abduction and 20 degrees of forward flexion (FIG 2).

Approach

- We use an all-arthroscopic technique for this procedure, with a posterior portal that is used as the main working portal (through the posterior deltoid) and an anterior portal (placed through the rotator interval) that is used for arthroscopic visualization.

FIG 1 • A. Axillary lateral radiograph that demonstrates glenoid hypoplasia, which predisposes to posterior instability of the shoulder. B. Axial image from an MR arthrogram that demonstrates a posterior labral lesion. Contrast can be seen between the posterior labrum and the articular margin of the glenoid, indicating a labral tear or avulsion.

FIG 2 • A. Lateral decubitus is the preferred position for arthroscopic surgery of the posterior capsule and labrum. B. The arm is placed in 10 to 15 pounds of traction and slightly abducted and forward flexed.
PORTAL PLACEMENT

- The glenohumeral joint is first injected (posteriorly) with 50 mL of sterile saline through an 18-gauge spinal needle.
- A posterior portal is established 1 cm distal and 1 cm lateral to the standard posterior portal that is used for routine shoulder arthroscopy. This portal is often in line with the lateral border of the acromion (TECH FIG 1A).
- Placement of this portal more laterally than typical allows adequate access to the posterior glenoid rim for later anchor placement.
- An anterior portal is established high in the rotator interval via an inside-out technique with a switching stick. As an alternative, this portal can be established with a spinal needle via an outside-in technique (TECH FIG 1B).
- The anterior switching stick is then replaced with an 8.25-mm distally threaded clear cannula.

TECH FIG 1 • A. The posterior portal (PP) is marked in line with the lateral border of the acromion (AC). B. Surface landmarks identify the posterior portal (PP), acromion (AC), anterior portal (AP), and coracoid process (CP).

DIAGNOSTIC ARTHROSCOPY

- With the arthroscope in the posterior portal, a diagnostic arthroscopy is performed.
- The articular surfaces of the glenohumeral joint are inspected for chondral damage. The posterolateral aspect of the humeral head is inspected for any Hill-Sachs lesions (which may indicate combined anterior instability).
- The anterior and inferior labrum is inspected and the glenohumeral ligaments are visualized.
- The biceps tendon and superior labrum are probed to detect any pathology. Concomitant SLAP tears are common with posterior instability.
- The rotator cuff is inspected (including the subscapularis tendon).
- A switching stick is then placed in the posterior portal and replaced with an additional 8.25-mm distally threaded clear cannula. The arthroscope is then replaced into the anterior cannula for viewing; it remains there for the rest of the operation.
- The posterior capsule and labrum are inspected and probed (TECH FIG 2).
- The anterior humeral head surface is inspected for any reverse Hill-Sachs lesions, which may indicate macroinstability.

TECH FIG 2 • A. Arthroscopic view from the posterior portal showing an avulsed posterior labrum. B. A complete avulsion of the labrum off the posterior glenoid is visualized from the posterior portal.
Chapter 3  ARTHROSCOPIC TREATMENT OF POSTERIOR SHOULDER INSTABILITY

PREPARATION OF THE GLENOID AND PLACEMENT OF SUTURE ANCHORS

- Typically the posterior labrum is detached and the capsule attenuated, requiring the placement of suture anchors.
- An arthroscopic rasp or chisel is used to mobilize the labrum from the glenoid rim.
- The rasp is then used to débride the capsule to create an optimal environment for healing.
- A motorized shaver or burr can be used on the glenoid rim to achieve a bleeding surface for healing.
- Suture anchors are placed along the articular margin, not the glenoid neck, for the repair and capsular plication (TECH FIG 3A).
- Typically we use three, 3-mm Bio-Suture Tak suture anchors with no. 2 FiberWire (Arthrex Inc., Naples, FL). A number of other commercially available anchors can be used in a similar fashion.
- The anchor pilot holes are predrilled and the anchor is inserted with a mallet.
- The anchor is placed so that the sutures are perpendicular to the glenoid rim. This facilitates passage of the most posterior suture through the torn labrum.
- The anchors are evenly spaced on the posterior glenoid rim for a symmetric repair (TECH FIG 3B).

![TECH FIG 3 • A. The anchor is placed on the glenoid margin. A drill is used to place a pilot hole before insertion of the anchor. B. The anchors are evenly spaced on the posterior glenoid margin to provide a symmetric and balanced repair.]

LABRAL AND CAPSULAR REPAIR

- A 45-degree Spectrum Hook (Linvatec Corp., Largo, FL) loaded with number 0 PDS suture (Ethicon, Somerville, NJ) is used to shuttle the suture through the capsule and labrum (TECH FIG 4A).
- The suture hook is delivered through the capsule (if a plication is warranted) and under the torn labrum at the articular margin of the glenoid.
- An inferior-to-superior direction is used for this maneuver to achieve a small capsular plication.
- This direction of suture passage is aimed at restoring tension to the posterior band of the inferior glenohumeral ligament.
- Patients with significant instability clinically may require a more aggressive plication than those with isolated pathology to the glenoid labrum.
- The PDS is fed into the glenohumeral joint and the passer is withdrawn.

![TECH FIG 4 • A. A suture hook is used to shuttle the anchor limb through the capsulolabral complex. B. The PDS suture has been passed through the capsule and posterior labrum. C. The anchor limb suture is then shuttled via the PDS suture. D. The sutures are tied using arthroscopic knot-tying techniques through the posterior portal, and the capsulolabral plication is finished.]

PEARLS AND PITFALLS

| Indications                                                                 | ■ A thorough history and examination with correlating radiographic studies help in determining the correct diagnosis.  
|                                                                           | ■ Patients should be counseled extensively on nonoperative therapy. |
| Patient positioning                                                       | ■ Debate exists as to which position allows better exposure of the posterior glenoid.  
|                                                                           | ■ The surgeon should feel comfortable with whichever position is chosen; however, we feel that the lateral decubitus position offers better visualization. |
| Portal placement                                                          | ■ Placing the posterior portal slightly lateral to the standard portal allows for easier placement of the anchors.  
|                                                                           | ■ Placing the anterior portal superior in the rotator interval allows better visualization. |
| Anchor placement                                                          | ■ Placing the anchors perpendicular to the glenoid margin and shuttling the posterior suture is paramount in preventing suture entanglement. |
| Repair                                                                    | ■ The repair should be tailored to the precise pathology of the patient as determined by the history, physical examination, and imaging studies. Patients without labral pathology may require an isolated plication.  
|                                                                           | ■ We prefer suture anchors regardless of which type of repair is necessary (capsule plication, capsulolabral plication, or labral repair). |
| Knot tying                                                                | ■ The surgeon should feel comfortable with both sliding and nonsliding knots before attempting arthroscopic repair techniques. |
**POSTOPERATIVE CARE**
- The patient leaves the operating room in an abduction sling that can be removed for passive range-of-motion exercises at home.
- We allow 90 degrees of forward elevation and external rotation to 0 degrees by 4 weeks after surgery.
- The sling is discontinued 6 weeks after surgery and active-assisted range-of-motion exercises and gentle passive range-of-motion exercises are progressed.
- Pain-free, gentle internal rotation exercises are instituted at 6 weeks.
- At 2 to 3 months after surgery, range of motion is progressed to achieve full passive and active range of motion.
- Stretching exercises can be instituted for any deficiency in motion at this point.
- After 4 months, the shoulder is often pain-free and eccentric rotator cuff strengthening is begun.
- At 5 months, isotonic and isokinetic exercises are advanced.
- At 6 months, throwing athletes undergo isokinetic strength testing.
  - If 80% of the strength and endurance of the contralateral extremity is attained, a throwing program is begun.
  - Full, competitive throwing is typically not attained until 12 months after surgery.
- Nonthrowing athletes are often released to a sport-specific program by 6 months, when 80% of their strength has returned.

**OUTCOMES**
- Arthroscopic posterior stabilization has achieved good results with respect to recurrence of instability and return to sport in athletes.
- Studies have shown rates of recurrence of 0% to 8% and rates of return to sport of 89% to 100%.

**COMPLICATIONS**
- Recurrent instability
- Stiffness
- Infection
- Neurovascular injury

**REFERENCES**
DEFINITION
- Neer and colleagues described the concept of multidirectional instability of the shoulder in detail in 1980.
- This established the difference between unidirectional instability and global laxity of the capsule inferiorly, posteriorly, and anteriorly.
- Subjective complaints of pain and global shoulder instability
- Subluxation or dislocation from traumatic, microtraumatic, or atraumatic injury

ANATOMY
- Stability of the shoulder relies on dynamic and static restraints.
- Static restraints:
  - Inferior glenohumeral ligament
    - Anterior band resists anterior translation in 90 degrees of abduction and external rotation.
    - Posterior band resists posterior translation in forward flexion, adduction, and internal rotation.
  - Middle glenohumeral ligament
    - Resists anterior translation in 45 degrees of abduction
  - Superior glenohumeral ligament
    - Resists posterior and inferior translation with arm at side
  - Rotator interval and coracohumeral ligament
    - Resists posterior and inferior translation with arm at side
- Dynamic restraints
  - Rotator cuff muscles
  - Deltoid
  - Effects of concavity and compression
- Shoulder instability has been found to be a result of several pathologic processes:
  - Capsular laxity
  - Labral detachment and Bankart lesion
  - Rotator interval defects

PATHOGENESIS
- Typically, there is not a history of a traumatic shoulder dislocation, but it may be the inciting event. Most commonly, the instability is due to microtrauma resulting in global capsular laxity.
- There may be a history of recurrent dislocations or repetitive subluxation events.
- Patients are typically young and active and present with the following:
  - Pain
  - Complaints of shoulder shifting
  - Difficulty with overhead activity
  - Inability to do sports
  - Instability while sleeping
  - Trouble with activities of daily living
  - Episodes of “dead arm” sensation
  - Failed prior attempts at physical therapy

NATURAL HISTORY
- Unable to change static restraints
- Stability can be achieved by restoring neuromuscular control through rehabilitation.
- Recurrent dislocations may lead to Hill-Sachs lesions, glenoid erosion, or chondral injury, which may predispose to early degenerative arthritis of the glenohumeral joint.
- Recurrent instability affecting daily activities despite formal physical therapy generally requires surgical treatment.

PHYSICAL FINDINGS
- Infrequent atrophy
- Symmetric range of motion
- Possible scapulothoracic winging
- Loss of active motion may be related to pain.
- Loss of passive motion may be from capsular contracture.
- Normal strength testing
- Loss of strength can indicate rotator cuff pathology or nerve injury.
- Evaluation for ligamentous laxity
  - Frequently positive for generalized ligamentous laxity
  - Predisposed to shoulder instability
- Evaluation for impingement. Impingement may be a sign of rotator cuff tendinitis or internal impingement in throwers.
- Stability testing
  - Positive increased load and shift test for anterior and posterior translation
  - Positive sulcus sign (both in neutral and external rotation) for inferior translation
  - A sulcus sign graded as 3+ that remains 2+ in external rotation is pathognomonic for multidirectional instability.
- Specific tests
  - Apprehension test: Positive result indicates anterior instability.
  - Relocation test: Positive result indicates anterior instability.
  - O’Brien sign: Pain or click indicates a superior labrum anterior posterior (SLAP) tear; anterosuperior pain indicates acromioclavicular joint pathology.
  - Jerk test: Positive result indicates posteroinferior instability.
  - Kim test: Positive result indicates posteroinferior instability.
  - Circumduction test: Positive result indicates posterior instability.
  - Speed’s test: Positive result indicates biceps tendinitis or SLAP tear.

IMAGING AND DIAGNOSTIC STUDIES
- Plain radiographs
- Anteroposterior view
■ Patients with voluntary or habitual instability

Contraindications
■ Patients who have not attempted a formal physiotherapy program should avoid initial surgical treatment.
■ Any patient unable or unwilling to comply with the postoperative rehabilitation regimen

Surgical Planning
■ Patient education is critical in planning surgical treatment for the patient with an unstable shoulder.
■ Patients should have failed a trial at nonoperative treatment and have persistent instability with functional deficits.
■ The goal of surgical treatment is to reduce capsular volume and restore glenoid concavity with capsulolabral augmentation.
■ Decreasing capsular volume may lead to decreased range of motion.
■ It is important to discuss this possibility with the patient because some more active athletic patients such as throwers, gymnasts, and volleyball players may not tolerate losses of motion to maintain participation in their sport.
■ Additional risks should be discussed, including infection, recurrence of instability, pain, neurovascular injury, persistent functional limitations, and implant complications.
■ The surgical planning continues with the evaluation under anesthesia and diagnostic arthroscopy.
■ This may alter the plan to include any combination of the following: capsular plication (anterior, posterior, or inferior), rotator interval closure, anteroposterior labral repair, SLAP repair, biceps tenodesis or tenotomy, and possible conversion to an open capsular shift.
■ Arthroscopic techniques have evolved from capsular shift via transglenoid sutures, Bankart repair and shift with biodegradable tacks or suture anchors, thermal capsulorrhaphy, rotator interval repair, and capsular plication.
■ Standard portals are listed in Table 2.
■ Our current method of treatment for patients with multidirectional shoulder instability who have failed to respond to nonoperative attempts is to perform an arthroscopic capsular shift by reducing capsular volume using capsular plication with a multipleted repair.18

NONOPERATIVE TREATMENT
■ In many patients with atraumatic multidirectional instability, proper neuromuscular control of dynamic glenohumeral stability has been lost.
■ The goal is to restore shoulder function through training and exercise.
■ Patients with loose shoulders may not necessarily be unstable, as evidenced by examining the contralateral asymptomatic shoulder in patients with symptomatic multidirectional instability.
■ The mainstay of treatment is nonoperative, with attempts to achieve stability using scapular and glenohumeral strengthening exercises.

SURGICAL TREATMENT

Indications
■ Patients who have attempted a dedicated program of physical therapy, have functional problems, and remain unstable may then be candidates for surgical treatment.
■ Patients with a history of multidirectional instability who sustain fractures of the glenoid or humeral head with a dislocation generally require surgical treatment.
■ Patients with significant defects in the humeral head associated with multiple dislocations consistent with Hill-Sachs lesions may require earlier surgical treatment.
■ Glenoid erosion or lip fractures, if significant, can also necessitate surgical intervention if associated with recurrent instability.

Contraindications
■ Patients with voluntary or habitual instability

Anesthesia and Patient Positioning

- The procedure can be performed under interscalene block or general endotracheal anesthesia with an interscalene block for postoperative pain control.
- The patient is then placed in the lateral decubitus position with the affected shoulder positioned superior.
  - An inflatable beanbag holds the patient in position.
  - Foam cushions are placed to protect the peroneal nerve at the neck of the fibula on the down leg.
  - An axillary roll is placed.
- The operating table is placed in a slight reverse-Trendelenburg position.
- The full upper extremity is prepared to the level of the sternum anteriorly and the medial border of the scapula posteriorly.
- The operative shoulder is placed in 10 pounds of traction and is positioned in 45 degrees of abduction and 20 degrees of forward flexion.
- Alternatively, the beach-chair position can be used. In our experience, however, this position gives limited exposure of the posterior inferior capsule.
- The head of the bed is raised to about 70 degrees with the affected shoulder off the side of the bed with support medial to the scapula.
- The head should be well supported and all bony prominences padded.
- The entire arm, shoulder, and trapezial region are prepared into the surgical field.

ESTABLISHING LANDMARKS AND PORTALS

- The bony landmarks, including the acromion, distal clavicle, acromioclavicular joint, and coracoid process, are demarcated with a marking pen (TECH FIG 1).
- After prepping and draping the patient, the gleno-humeral joint is injected with 50 mL of sterile saline through an 18-gauge spinal needle to inflate the joint.
- A posterior portal can be established 1 cm proximal (high) and 1 cm lateral (humeral) to the standard posterior portal to allow access to the rim of the posterior glenoid for anchor placement if a posterior labral or capsular repair is necessary.
- An anterior portal is then established in the rotator interval via an outside-in technique using a spinal needle.
  - Care should be taken using the switching stick to verify that the low anterior inferior 5 o'clock anchor can be placed through this portal.
  - If two anterior portals are desired, this portal should be placed “high” in the interval to make room for the second “low” portal.
  - Typically, an additional anteroinferior portal is unnecessary using our multipleated technique.

If a second portal is desired, it is created using a spinal needle at the level just superior to the subscapularis tendon lateral to the coracoid and at least 1 cm inferior to the anterior portal.

TEST FIG 1 • Arthroscopic portals.

DIAGNOSTIC ARTHROSCOPY

- The examination under anesthesia is performed on a firm surface with the scapula relatively fixed and the humeral head free to rotate.
  - A “load and shift” maneuver, as described by Murrell and Warren,13 is performed with the patient supine.
  - The arm is held in 90 degrees of abduction and neutral rotation while an anterior or posterior force is applied in an attempt to translate the humeral head over the anterior or posterior glenoid.
  - A “sulcus sign” is performed with the arm adducted and in neutral rotation to assess whether the instability has an inferior component.
  - A 3+ sulcus sign that remains 2+ or greater in external rotation is considered pathognomonic for multidirectional instability.
- Testing is completed on both the affected and unaffected shoulders, and differences between the two are documented.
- Diagnostic arthroscopy of the glenohumeral joint
  - The labrum, capsule, biceps tendon, subscapularis, rotator interval, rotator cuff, and articular surfaces are visualized in systematic fashion.
  - This ensures that no associated lesions will be overlooked.
- Lesions typically seen in multidirectional instability include:
  - Patulous inferior capsule
  - Labral tears (TECH FIG 2) or fraying and splitting
  - Widening of the rotator interval
  - Articular partial-thickness rotator cuff tears
PREPARATION FOR REPAIR

- The arthroscope remains in the posterior portal and the anterior portals serve as the working portal for the anterior repair and vice versa for the posterior repair.
- The side (anterior or posterior) that is least unstable is fixed first. For example, if posterior instability is the most severe direction, the anterior and inferior sides are fixed first and the posterior capsule and labrum is addressed last.
- After viewing the glenohumeral joint from the posterior portal, the arthroscope is switched to the anterior portal to allow improved visualization of the posterior capsule and labrum.
- A switching stick can then be used in replacing the posterior cannula with an 8.25-mm distally threaded or fully threaded clear cannula (Arthrex Inc., Naples, FL), thus allowing passage of an arthroscopic probe and other instruments through the clear cannula to explore the posterior labrum for evidence of tears.
- An arthroscopic rasp or chisel is used to mobilize any torn labrum from the glenoid rim (TECH FIG 3A).
- A motorized synovial shaver or meniscal rasp is used to abrade the capsule adjacent to a labral tear and to débride and decorticate the glenoid rim to achieve a bleeding surface for capsular plication (TECH FIG 3B).

MULTIPLEATED Plication

- A 3.0-mm Bio-Suture Tak anchor loaded with no. 2 FiberWire (Arthrex, Naples, FL) is placed in the 5 o’clock position (right shoulder) for the anterior repair and the 7 o’clock position for the posterior repair and the sutures are brought out through the working portal (TECH FIG 4A,B).19
- A soft tissue penetrator (Spectrum Suture Hook, Linvatec, Largo, FL) or crescent suture passer is passed through the labrum directly adjacent to the anchor and the inferior FiberWire on the anchor is pulled through the labrum (TECH FIG 4C).
- The penetrator is then used to pierce the inferior capsule in the most anteroinferior (5 o’clock anchor) and lateral point or posteroinferior (7 o’clock anchor) and lateral point.
- Once through the capsule, a no. 1 PDS suture (Ethicon, Johnson & Johnson, Somerville, NJ) is shuttled into the joint and the penetrator is removed (TECH FIG 4D).
- A suture grasper is then used to grab both the passed PDS suture and the labral suture and pull them out of the same portal, or the working portal if two portals are used.
- The PDS suture is tied with a simple knot to the FiberWire and then used to shuttle the working suture through the inferior tuck of capsule (TECH FIG 4E).
- This simple process is repeated while moving superiorly up the capsule until adequate capsular tension is restored (TECH FIG 4F). This can be done multiple times until adequate capsular tension is achieved with each suture.
- The suture is checked to ensure it will still slide, and then a locking sliding knot backed with three half-hitches is tied. The remaining suture is then cut (TECH FIG 4G).
- This is begun posteriorly and inferiorly (7 o’clock anchor), working posterior with additional anchors as necessary (TECH FIG 4H), and then anterior and inferiorly (5 o’clock anchor), working up anterior, again using additional anchors as necessary (TECH FIG 4I). This would be the case if anterior instability is the most severe direction. If posterior instability is predominant, then the plication would begin anteriorly and inferiorly and then finish posteriorly.
- The completed multipleated capsular plication reduces volume and improves stability (TECH FIG 4J).
**ARTHROSCOPIC KNOT TYING**

- We prefer the sliding, locking Weston knot, but a number of arthroscopic knot-tying techniques work well.
- What is most important is that the surgeon is familiar with the knot used and skilled in its use.
- The posterior braided suture exiting through the capsule is threaded through a knot-pusher and the end is secured with a hemostat.
- This suture serves as the post, which in effect will advance the capsule and labrum to the glenoid rim when the knot is tightened.
- The knot should be secured posteriorly on the capsule, not on the rim of the glenoid, to prevent humeral head abrasion from the knot.
- Each half-hitch must be completely seated before the next half-hitch is thrown.
- Placing tension on the non-post suture and advancing the knot-pusher "past point" will lock the Weston knot.
- A total of three alternating half-hitches are placed to secure the Weston knot.
- This knot has been found to be biomechanically similar to an open square knot.\(^4\)

**ROTATOR INTERVAL CLOSURE**

- In the setting of multidirectional instability, the rotator interval may not require closure (defined by a 2+/ or greater sulcus sign that does not improve in external rotation) if a multipleated repair is performed both anteriorly and posteriorly to bring up the entire axillary pouch.\(^16\)
- However, if rotator interval closure is required, it is viewed with the arthroscope in the posterior portal.
- A crescent suture passer is advanced from the anterior portal through the anterior capsule just above the superior border of the subscapularis tendon 1 cm lateral to the glenoid.
- It is then passed through the middle glenohumeral ligament at the inferior border of the rotator interval. This makes up the inferior aspect of the rotator interval closure.
- A no. 0 PDS suture is then fed into the joint and retrieved with a penetrator through the superior glenohumeral ligament.
- The PDS suture is then withdrawn out the anterior cannula and exchanged for a no. 2 FiberWire. The knot is then tied blindly in the cannula on the outside of the anterior capsule as the closure is visualized through the posterior portal.

**POSTERIOR PORTAL CLOSURE**

- A crescent suture passer is advanced from the posterior portal through the posterior capsule just above the superior border of the capsular opening of the posterior portal (TECH FIG 5A).
- A no. 0 PDS suture is then fed into the joint and retrieved with a penetrator through the inferior border of the capsular opening in the posterior portal (TECH FIG 5B).
- The PDS suture is then withdrawn out the posterior cannula and exchanged for a no. 2 FiberWire. The knot is tied blindly in the cannula on the outside of the posterior capsule as the closure is visualized through the anterior portal (TECH FIG 5C).

---

**TECH FIG 5**

A. Placing crescent suture passer through posterior capsular and passing PDS suture into the joint.
B. Passing suture grasper through posterior capsule for closure of posterior portal.
C. Completed closure of the posterior portal after capsular plication.
POSTOPERATIVE CARE

■ The patient is discharged home on the day of surgery.
■ The sutures are removed 6 to 8 days later.
■ The arm is immobilized in an Ultrasling (DonJoy, Carlsbad, CA) for 6 weeks (30 degrees abduction in neutral rotation).
■ The sling is removed for bathing and for gentle pendulum and elbow, wrist, and hand range-of-motion exercises.
■ Isometric exercises are started at week 3, passive and active-assisted range-of-motion exercises at week 3.
■ Sling is discontinued at week 6.
■ Active range of motion is started at week 6.
■ Sport-specific exercises are started at 4 months.
■ Overhead sports are started at 6 months.
■ The patient can return to contact sports at 6 to 8 months.

OUTCOMES

■ Table 3 summarizes outcomes of clinical studies.
■ Several studies have investigated the effect of surgical intervention on capsular volume.
■ Comparisons have been made between open capsular shifts using numerous techniques, arthroscopic thermal plications, and arthroscopic suture capsular plications by testing capsular volume in cadaveric specimens before and after procedures.
■ Table 4 summarizes the results and type of shift performed in these studies.

Chapter 4  ARTHROSCOPIC TREATMENT OF MULTIDIRECTIONAL SHOULDER INSTABILITY

COMPLICATIONS

- Loss of motion
- Recurrence of instability
- Neurovascular injury
- Failure to address missed causes of instability
- Large Hill-Sachs lesions that cause instability and are not addressed at surgery may lead to recurrence.20

REFERENCES

DEFINITION
- Superior labral (SLAP) tears represent injury to the superior aspect of the glenoid labrum, extending from anterior to posterior, including the biceps anchor.14

ANATOMY
- The superior glenoid labrum is composed of fibrocartilaginous tissue between the hyaline cartilage of the glenoid surface and the joint capsule fibrous tissue.13
- The vascular supply of the glenoid labrum does not come from the underlying glenoid, but rather from penetrating branches of the suprascapular, circumflex scapular, and posterior humeral circumflex arteries in the surrounding capsule and periosteal tissue.
- There is histologic evidence that vascularity is decreased in the anterior, anterosuperior, and superior aspects of the glenoid labrum.2

PATHOGENESIS
- The long head of the biceps functions to depress the humeral head and serves as an adjunct anterior stabilizer of the shoulder.5,6
- Disruption of the biceps anchor and the superior labrum, as seen in type II SLAP tears, can result in glenohumeral instability.
- Although SLAP tears are commonly associated with trauma such as traction or compression injuries, up to one third of patients with SLAP lesions have no history of trauma.10
- SLAP tears are commonly classified according to Snyder14 as type I (fraying of superior labrum with intact biceps anchor), type II (detached superior labrum and biceps anchor), type III (bucket-handle tear of the superior labrum with intact biceps anchor), and type IV (bucket-handle tear of the superior labrum with extension into the biceps tendon).
- Other variations have been described that reflect associated injury to the anterior labrum and other structures.8

NATURAL HISTORY
- Conservative nonoperative treatment of SLAP tears is usually unsuccessful.
- Simple débridement of unstable SLAP tears (type II and IV) is generally not recommended because the results are poor.3

PATIENT HISTORY AND PHYSICAL FINDINGS
- Traction and compression are the two primary mechanisms of injury for SLAP tears.
- A SLAP tear should be considered in a patient with a history of a traction or compression injury with persistent mechanical symptoms such as catching or locking.
- Several clinical tests have been described that focus on the examination of the biceps tendon anchor on the superior glenoid. The Speed, Yergason, O’Brien, and load-compression tests are commonly used.
  - Speed and Yergason tests: Pain with the maneuvers suggests a SLAP tear.
  - O’Brien test: Pain with downward pressure applied to the internally rotated arm that is relieved with supination suggests a SLAP tear.
  - Load-compression test: Painful clicking or popping suggests a SLAP tear.
- Type II SLAP tears found in younger patients are commonly associated with instability and a Bankart lesion, whereas type II SLAP tears found in patients older than 40 are often associated with rotator cuff pathology.7
- Although no single clinical test can predictably be used to diagnose a SLAP tear, the examiner should use all of these tests, along with the history and a high clinical index of suspicion, to make the diagnosis of a SLAP tear.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Although conventional radiographs (anteroposterior and supraspinatus outlet and axillary views) are the standard for initial evaluation of a patient with shoulder complaints, magnetic resonance imaging (MRI) is the most sensitive imaging tool for evaluating the superior glenoid labrum, with a sensitivity and specificity of about 90%.1
- The use of contrast arthrography MRI may improve the overall accuracy of MR for diagnosing SLAP tears.9
- Despite advances in imaging techniques, the gold standard for the diagnosis of a SLAP tear is arthroscopy.

DIFFERENTIAL DIAGNOSIS
- Glenohumeral instability
- Rotator cuff pathology
- Acromioclavicular joint pathology

NONOPERATIVE MANAGEMENT
- Physical therapy is the mainstay of nonoperative treatment of most shoulder injuries.
- Selective intra-articular injections with local anesthetic and corticosteroids can be diagnostic and occasionally therapeutic.
- The rehabilitation program should focus on achieving and maintaining a full range of motion and strengthening the rotator cuff and scapula stabilizers.
- Although physical therapy may be useful for regaining range of motion and strength, most patients with SLAP tears will continue to have symptoms despite physical therapy.

SURGICAL MANAGEMENT
- Surgical treatment of SLAP tears should be considered for patients who have persistent symptoms despite appropriate conservative management.
Chapter 5  ARTHROSCOPIC TREATMENT OF SUPERIOR LABRAL (SLAP) TEARS

- Contraindications for SLAP repair include patients who are high-risk surgical candidates (ie, the risk of anesthetic complications outweighs the possible benefits of successful repair).

Preoperative Planning
- Preoperative assessment of glenohumeral instability is paramount to understanding the pathophysiology of a patient’s shoulder complaints.
- Associated instability and any other coexisting pathology must also be addressed at the time of SLAP repair.

Positioning
- Beach-chair position
- Lateral decubitus position
  - May be preferred for cases of suspected labral pathology, especially if associated with posterior instability, because this position allows improved visualization and access with distraction.

- No more than 10 to 15 pounds of traction should be used owing to increased risk of brachial plexus injuries.

Approach
- The primary goal of any SLAP repair is to stabilize the biceps anchor and address any coexisting pathology.
- After a thorough diagnostic evaluation, SLAP lesions are treated according to Snyder14 (see the Techniques section).
  - Standard anterosuperior and anteroinferior portals are established.
  - Accessory portals may also be established depending on the location of the SLAP tear.

**TYPE I SLAP TEARS**
- Type I SLAP tears may be treated using a motorized shaver to simply débride the degenerative or frayed tissue.

- Care must be taken not to detach the biceps anchor from the superior glenoid.

**TYPE II SLAP TEARS**
- Type II SLAP tears are the most commonly encountered SLAP tears (TECH FIG 1).
  - They represent detachment of the biceps anchor from the superior glenoid labrum.
  - As such, the primary goal of any repair should be to securely reattach the superior labral tissue to the superior glenoid.

Glenoid Preparation
- After identifying the detachment by direct probing, a 4.5-mm motorized shaver is used to gently débride any frayed or degenerative tissue.
- A motorized burr is used to débride the superior glenoid to exposed, bleeding bone (TECH FIG 2).

Accessory Portal Placement
- An accessory trans-rotar cuff portal is made using an outside-in technique. No cannula is inserted because this portal will be used only to insert the anchor.

  This portal may be adjusted anteriorly or posteriorly depending on the location of the SLAP tear.
  - A spinal needle is used to ensure that the correct trajectory is achieved to place the anchor at about a 45-degree angle to the glenoid face.
  - A no. 11 blade knife is used to make the skin incision, but a cannula is not inserted because this portal will be used only to insert the suture anchor drill guide and anchor after drilling.

Suture Anchor Placement
- The suture anchor drill guide is placed on the glenoid face at about a 45-degree angle to the face, ensuring that the anchor will be solidly in bone (TECH FIG 3).
  - The suture anchor may be single- or double-loaded with nonabsorbable no. 2 braided suture, depending on preference.
  - If more than one suture anchor is to be used, the surgeon starts the repair posteriorly and works anteriorly to aid in visualization.
  - The anchor is placed in the same trajectory as the drill, ensuring that the drill guide is maintained in its proper orientation and position.

**TECH FIG 1** • Arthroscopic view of type II superior labral anterior posterior (SLAP) lesion.

**TECH FIG 2** • Preparing superior glenoid with burr.
Suture Management

- One limb (limb a) of the suture is retrieved out through the anterior superior cannula, using either a crochet hook or suture grasper.
- A crochet hook is used to capture the other limb (limb b) of the anchor suture and bring it out the anterior inferior cannula (TECH FIG 4).

Suture Passage

- Through the anterosuperior cannula and starting at the posterior edge of the tear superiorly, the surgeon passes a tissue penetrator (Spectrum, ConMed Linvatec, Largo, FL) through the labrum (TECH FIG 5A,B).
  - A 45-degree left-curved tissue penetrator is used for a right shoulder SLAP tear (45-degree right-curved for the left shoulder) loaded with a no. 1 monofilament or Shuttle Relay suture passer (ConMed Linvatec, Largo, FL) as a pull-through suture.
  - An arthroscopic grasper inserted through the anteroinferior cannula is used to grasp the monofilament passing suture as it penetrates the superior labrum, and the free end is pulled out through the anteroinferior cannula (TECH FIG 5C,D).
  - A simple knot is tied in the passing suture (see Tech Fig 5D, inset) and the free end of limb b from the suture an-
Simple débridement of the labral bucket-handle tear is the preferred surgical technique for type III SLAP tears because the biceps anchor is intact.

**TYPE III SLAP TEARS**

- Simple débridement of the labral bucket-handle tear is the preferred surgical technique for type III SLAP tears because the biceps anchor is intact.

**Knot Tying**
- Making sure that the post limb is off the glenoid surface, the surgeon ties the suture using either a sliding knot or a series of half-hitches, taking care to switch posts and alternate directions of the loops.
- The excess suture is cut using an arthroscopic suture cutter.

**Additional Suture Anchor Placement**
- This procedure is repeated until the biceps anchor has been securely reattached to the superior glenoid (TECH FIG 6).
- The surgeon should take care when securing the anterior aspect of the SLAP tears so that a normal labral foramen or an anterosuperior labral variant is not incorrectly identified as a SLAP tear, causing inadvertent tightness and resulting in decreased range of motion.

**Tech FIG 5 (continued)**
- The surgeon firmly pulls the shuttle relay suture through the anterosuperior cannula so that the two ends of the anchor suture are together in the anterosuperior cannula.

**Tech FIG 6**
- Completed superior labral anterior posterior (SLAP) lesion repair.
## Type IV SLAP Tears

- Type IV SLAP tears involve a bucket-handle tear of the superior labrum with a tear of the biceps tendon.
- The biceps anchor may be detached as well.
- Treatment is débridement of the labral tear and biceps tendon tear, with repair of the biceps anchor if needed, essentially converting the tear to a type II and then repairing the anchor detachment.
- In an older patient with significant biceps tendon degeneration, biceps tenodesis should be considered.
- Similarly, in a younger patient with a tear extending into the biceps tendon, repair of any tendon tears should be considered.

## Pearls and Pitfalls

### Indications
- All associated pathology is identified and addressed (eg, instability, rotator cuff pathology, acromioclavicular joint disorders).

### Planning
- Lateral decubitus positioning is considered if posterior labral pathology is suspected.

### Portal Placement
- Proper technique must be used in placing portals at the beginning of the case, with attention to positioning of the portals both in the superoinferior plane and the medial-lateral plane. Improperly placed portals can greatly increase the difficulty of this operation. A spinal needle is used to judge the angle of approach for each portal before making the portal to ensure that the correct trajectory is obtained.

### Suture Management
- When retrieving and handling anchor sutures, the surgeon should not place tension on either limb and should maintain continuous visualization of the anchor–suture interface to ensure that the anchor is not unloaded. The surgeon should take care to avoid twists because these can place increased stress on a suture or knot and lead to breakage. The surgeon should place one anchor at a time and tie each suture or remove and replace the cannula and place the suture outside the cannula for suture storage to prevent tangles during tying.

### Other
- Articular cartilage damage is avoided by firmly seating the drill guide on the edge of the glenoid and avoiding skiving onto the glenoid face.

## Postoperative Care

- 0 to 4 weeks: Sling at all times except for hygiene and exercises. (Active range of motion allowed in all planes except external rotation in abduction starting at 2 weeks.)
- 4 weeks: Discontinue sling. Start passive range of motion with emphasis on posterior capsule stretching.
- 6 weeks: External rotation in abduction allowed. Start strengthening.
- 3 months: Sports allowed except throwing (4 months)

## Outcomes

Table 1 summarizes outcomes from studies of SLAP tear repairs.

ASES, American Shoulder and Elbow Society.
■ Failed repair
■ Repeat arthroscopy should be considered with revision repair.
■ Biceps tenodesis should be considered for severely degenerative or intractable cases.

REFERENCES
DEFINITION

- Throwers place unique stress on their shoulder girdles due to the repetitive nature and magnitude of force associated with the activity.
- Throwing athletes are prone to shoulder dysfunction due to chronic fatigue and weakening of the posterior shoulder musculature that over time leads to maladaptive contracture of the posterosuperior glenohumeral joint capsule.\(^5\)
- Posterosuperior capsular contracture alters the biomechanics of the glenohumeral joint during the throwing motion and produces a predictable constellation of injuries in disabled throwers, including superior labral and biceps anchor disruption, undersurface progressing to full-thickness rotator cuff tears, and disruption of the anteroinferior capsule or labrum.\(^3\)
- Symptoms resulting from these injuries have commonly been referred to as the “dead arm syndrome,” where the athlete cannot compete at the premorbid level due to shoulder discomfort with throwing and resultant loss of pitch velocity and control.\(^3\)
- Although most often seen in pitchers, similar shoulder dysfunction may occur in baseball position players as well as athletes in other sports requiring forceful and repetitive overhead activity.

ANATOMY

- Eighteen muscles attach to the scapula and control its position on the chest wall.
  - Scapular position dictates glenoid position and orientation and is critical for normal glenohumeral function.
  - A force of up to 1.5 times body weight is generated during the throwing cycle. The scapular stabilizers and posterior rotator cuff muscles contract violently at ball release and protect the glenohumeral joint from the deceleration force of the arm.
  - The relative position of the glenohumeral ligaments with different arm positions. As the arm is brought into full abduction and external rotation (late cocking phase), the posterior band of the inferior glenohumeral ligament complex (PIGHL) moves from a posterosuperior position to a position directly inferior (6 o’clock) in relation to the glenoid.\(^3\)

PATHOGENESIS

- Posterior shoulder muscle weakness due to chronic, repetitive loading is the inciting lesion causing disability in throwers.
- Posterior muscle weakness leads to shoulder dysfunction as a result of both scapular dyskinesis and PIGHL contracture. One of these pathologic entities may predominate in the disabled thrower, but they are generally intimately related.\(^3\)
- In scapular dyskinesis, the position of the scapula on the chest wall (or “scapular attitude”) is altered owing to loss of scapular elevation and retraction control. The scapula drops (infera), moves lateral from the midline (protraction), and abducts from the midline. The inferior scapular angle may also lift off the chest wall and pitch toward the front of the body (antetilt).
  - The predominant direction of these positional changes will vary depending on which scapular muscles are predominantly affected.
  - Altered scapular position causes abnormal tension on the insertion of scapular stabilizer muscles and over time leads to inflammation and pain (“traction tendinopathy”).\(^5\)
  - PIGHL contracture involves failure of the weakened posterior shoulder muscles to counteract the distraction force of the arm after ball release exposes the PIGHL to abnormal stress due to the forward-flexed and adducted position of the arm at follow-through. Fibroblastic thickening and contracture of the PIGHL occur as a maladaptive response to greater stress (Wolf’s law of collagen).
  - PIGHL contracture can be identified clinically as a scapular-stabilized glenohumeral internal rotation deficit (GIRD) in the throwing shoulder (designated by subscript “ts”) versus nonthrowing shoulder (subscript “nts”).\(^3\)
  - The thickened PIGHL alters the normal biomechanics of the glenohumeral joint, particularly as the arm is brought into abduction and external rotation (late cocking phase). The normal glenohumeral contact point is shifted posteriorly and superiorly due to the thickened and contracted PIGHL occupying a position directly inferior to the humeral head in this arm position (FIG 1A,B).\(^6\)
  - Alteration of the glenohumeral contact point leads to a predictable pathologic cascade with continued throwing.\(^3\)
    - Posterosuperior shift allows greater clearance of the tuberosity over the posterosuperior glenoid rim, enabling pathologic hyperexternal rotation of the arm in the late cocking phase.
    - Increased external rotation of the throwing shoulder is adaptive in these athletes to some extent (used to maximize throwing arc and angular velocity at ball release).\(^3\)
  - However, pathologic hyperexternal rotation leads to:
    - An abnormal posteriorly directed force vector and torsion on the biceps anchor. The biceps anchor ultimately fails and “peels back” medially along the posterosuperior glenoid neck (the “SLAP event”). SLAP tears are typically anterior and posterior or posterior subtypes of type II tears (the “thrower’s SLAP”).\(^8\)
    - Rotator cuff tears occur because of abrasion and torsion of tendon fibers. Torsion failure is most pronounced on the articular side of the tendons, resulting in partial undersurface tears most commonly seen in throwers. These tears may at times progress to full thickness with continued throwing.
    - Posterosuperior shift of the glenohumeral contact point causes relative relaxation and “pseudo-laxity” in the anterior capsule (FIG 1C,D). With continued hyperexternal rotation, tension may ultimately cause anteroinferior capsular fiber attenuation, leading to tertiary anterior glenohumeral instability, which occurs in about 10% of
affected athletes. Discrete “Bankart-type” lesions of the labrum occasionally occur in this group. Anterior instability is a later event in the pathologic cascade, not the primary lesion as previously described.7

**NATURAL HISTORY**

- Athletes manifesting clinical findings of posterior muscle weakness and scapular asymmetry without signs of labral or rotator cuff pathology may correct their shoulder dysfunction with a progressive scapular muscle strengthening program and return to normal function when asymmetry resolves.
- Throwers who have vague shoulder discomfort and demonstrate an internal rotation deficit (GIRD) are started on focused internal rotation stretches (“sleeper” stretches) to alleviate PIGHL contracture and restore normal glenohumeral biomechanics. GIRD reduction to less than 20 degrees removes the athlete from being at risk for shoulder injury and generally allows return to premorbid function.

**FIG 1** • A,B. Depiction of altered glenohumeral biomechanics due to an acquired posterior band of the inferior glenohumeral ligament complex (PIGHL) contracture and the resulting posterosuperior shift in the glenohumeral contact point as the arm is brought from neutral (A) to full abduction and external rotation (B), or late cocking phase. In the fully cocked position, the PIGHL occupies a position inferior to the humeral head, which forces the humeral head superiorly and tethers it posteriorly.
- C,D. Drawings in the axial plane showing relative relaxation of the anterior capsule in the late cocking position as a result of the posterosuperior shift in the glenohumeral contact point in a shoulder with PIGHL contracture.
- In a normal shoulder, the anterior capsule is taut over the cam shape of the humeral head. In PIGHL contracture, the humeral head shifts posteriorly, which decreases tension in the anterior capsule, creating relative laxity. C, center of glenoid.
Pain with throwing is indicative of injury to glenohumeral structures.
- Once actual injury to glenohumeral structures, particularly the labrum, has occurred, mechanical symptoms ensue and the thrower will not be able to return to normal function without surgical repair.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Common early complaints include vague tightness in the shoulder and a difficulty or inability to “get loose” during a warm-up period.
- Pitchers describe a loss of control and decrease in throwing velocity, which early on may be pain-free.
- Pain is most prominent during the late cocking phase of throwing when the peel-back phenomenon of the superior labrum occurs, caused by the posterosuperior glenohumeral shift.4
  - Pain is localized to the posterosuperior shoulder and is described as “deep.”
  - Mechanical symptoms, such as painful popping or clicking, may occur after injury to the superior labrum, particularly during late cocking and early acceleration.
- The surgeon should check for tenderness in the coracoid, the acromioclavicular joint, and the superomedial scapular angle.
- Both shoulder girdles must be completely exposed or subtle asymmetry will be overlooked.
  - Inspection is done with the patient standing in front of fixed vertical and horizontal references (such as window blinds or door frames) so that affected and nonaffected shoulders can be compared for scapular height and malposition (FIG 2).
  - Superior and inferior angles as well as the medial scapular border are marked as a visual reference. Spinous processes are marked for a midline reference.
  - Asymmetry from the unaffected side when in protraction or infera indicates scapular stabilizer muscle weakness.
  - When in abduction or antetilt, increasing magnitude compared to opposite side signifies scapular muscle weakness.
  - Range-of-motion measurements are performed in the supine position with the scapula stabilized by anterior pressure over the glenohumeral joint directed into the examination table, which prevents contribution of scapulothoracic motion. Nonstabilized measurements will be erroneously high and will not reveal the true magnitude of glenohumeral pathology.
- Measurements are made using a special goniometer that incorporates a carpenter’s bubble level to provide a vertical reference point (perpendicular to floor) from which measurements are made.
- External rotation (ER) + internal rotation (IR) = total mobility arch (TMA)
  - IR\textsubscript{as} - IR\textsubscript{ts} = glenohumeral internal rotation deficit (GIRD)
  - TMA\textsubscript{as} \approx TMA\textsubscript{ts} in healthy throwers
  - GIRD\textsubscript{a} > 20 degrees seen in “shoulders at risk” for injury; generally GIRD\textsubscript{a} \approx loss of TMA\textsubscript{ts} vs. TMA\textsubscript{as}
- Scapular relocation tests are performed in the supine position with the arm maximally forward-flexed. A positive test is indicated by pectoralis minor tension that is accentuated with the arm forward-flexed; traction at the coracoid insertion is relieved by scapular repositioning.
  - The specificity of tests for type II SLAP lesions in throwers has been determined as follows:5
    - The modified Jobe relocation test is specific for posterior subtype. In throwers with SLAP tears, their usual pain is reproduced and they will localize to the posterosuperior joint line (“deep”). Pain in the abduction and external rotation (ABER) position is due to an unstable labrum; anterior pressure reduces the labrum and relieves pain.
    - O’Brien’s test is specific for anterior subtype. A positive result is defined as pain with resisted forward flexion and pronation; pain is diminished or relieved with supination.
    - The Speed test is specific for anterior subtype. A positive result is defined as pain with resisted forward flexion.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs: anteroposterior (AP), scapular lateral, and axillary views to detect bone or joint space abnormalities
- Magnetic resonance (MR) arthrography: We routinely order intra-articular contrast material because it improves the ability to detect labral and capsular abnormalities as well as partial-thickness rotator cuff tears (FIG 3).

FIG 2 • Thrower with right scapular dyskinesis. Scapular asymmetry is highlighted by marking the superior and inferior scapular angles as well as the midpoint of the medial border. Affected right side shows scapular infera and protraction compared to the unaffected left side.

FIG 3 • Coronal MRI arthrogram study. The vertically oriented high-signal lesion in the substance of the biceps anchor (circle) suggests a superior labrum anterior-to-posterior (SLAP) tear. In addition, there is evidence of partial undersurface tearing of the supraspinatus tendon.
DIFFERENTIAL DIAGNOSIS
- Subacromial irritation secondary to rotator cuff weakness and dysfunction
- Various forms of anterior shoulder pain, acromioclavicular joint dysfunction, and posterior periscapular pain secondary to scapular dyskinesis and the SICK scapula syndrome (Scapular malposition, Inferior medial scapular winging, Coracoid tenderness, and scapular dyskinesis).5
- Pain with throwing may occur with rare conditions such as bone tumors, stress fractures, and growth plate abnormalities.

NONOPERATIVE MANAGEMENT
- Symptomatic athletes are begun on a scapular reconditioning program combined with internal rotation posteroinferior capsular “sleeper” stretches.
- Scapular reconditioning focuses on regaining scapular elevation and retraction control; progress is assessed by repeat examination for normalization of scapular symmetry.
  - Initially bilateral shoulder shrugs and rolls are combined with retraction “no money” exercises.
  - The patient progresses to closed-chain “table top” movements and wall-washing motions.
  - Finally, prone “Blackburn”-type exercises are instituted.
- “Sleeper” stretches focus on the posteroinferior capsular contracture that initiates the internal derangement in the glenohumeral joint (FIG 4). Response to a course of internal rotation stretching will determine the extent of the PIGHL contracture.
  - 90% of athletes will decrease their GIRD to an acceptable magnitude with 10 to 14 days of focused stretching (less than 20 degrees) with near-normalization of TMA<sub>Ants</sub> and TMA<sub>Ans</sub>.
  - The remaining 10% have recalcitrant PIGHL contracture and will show little or no decrease in GIRD after a period of stretching; they are termed stretch nonresponders. These are generally veteran athletes with longstanding GIRD and may require posteroinferior quadrant capsulotomy to regain internal rotation.

SURGICAL MANAGEMENT
- Athletes presenting with pain and mechanical symptoms during throwing as well as findings suggestive of intra-articular pathology on MR arthrogram are indicated for arthroscopic evaluation and treatment.
- Rarely, posteroinferior capsulotomy is indicated in throwers unresponsive to internal rotation stretching to decrease GIRD. This portion of the procedure is almost never necessary in a young thrower, however.
- Contraindications to the surgical technique below include those similar to other elective arthroscopic shoulder procedures.

Preoperative Planning
- Surgical treatment of the throwing shoulder may involve repair of the superior labrum as well as associated injuries to the rotator cuff and anterior capsulolabral structures, as well as contracture of the posteroinferior capsule.
  - All pathology must be anticipated before beginning the case, and all necessary instruments and materials need to be present on the back table to prevent intraoperative delays.
  - A fluid pump is used during the procedure to distend the joint and limit bleeding to improve visualization (set at 60 mm Hg). Prolonged procedures increase the risk of having to perform the surgery through distended tissue, which makes instrument manipulation in the joint difficult and can severely compromise the procedure.
  - The following order of possible intra-articular repairs is recommended to ease visualization and prevent loss of access to various locations in the joint:
    - Anteroinferior labral repair (if required)
    - Posterior SLAP repair
    - Anterior SLAP repair
    - Anterior capsular redundancy (if present)
    - Posteroinferior capsulotomy (if required)
    - Rotator cuff tear (if present)

Treatment of Associated Injury
- We débride partial-thickness rotator cuff tears that represent less than 50% of the diameter and repair those larger than 50% of the diameter as described in Chapter SM-10.
  - Given the young age and high-level activity of these athletes, strong consideration should be given to repair in borderline cases.
- Anteroinferior capsulolabral injury
  - Throwers may develop stretching and attenuation of the anteroinferior capsule, separation of the anteroinferior labrum from the glenoid rim, or a combination of the two.
  - We perform mini-plication of the anterior capsule in the following circumstances:
    - Evidence of frayed or attenuated anterior capsule with intact anterior labrum
    - A persistent drive-through sign after superior labral repair, or more than 120 degrees of external rotation at 90 degrees of abduction noted during the preoperative examination
    - Posterior capsular release is rarely indicated (about 10% of cases).
  - Response to internal rotation stretching is assessed preoperatively.
Patients displaying little to no response to stretching (unable to attain GIRD less than 20 degrees) are indicated for capsulotomy to allow restoration of full motion and normal glenohumeral biomechanics.

Positioning
- A preoperative intrascalene nerve block is recommended to improve pain control postoperatively.
- Antibiotics for skin flora are administered.
- The patient is in the lateral decubitus position using an inflatable beanbag.
- The arm is secured to a rope and pulley system that is attached to 10 pounds of weight.
- A spring-gated, carabiner-type device is added between the end of the traction cord and the suspension pulley so that an unscrubbed assistant can remove the arm from traction during the procedure for dynamic diagnostic maneuvers (see below).
- Advantages of the lateral decubitus position include:
  - Better visualization of the superior labrum and widening of the superior recess due to gravity for easier anchor placement and knot tying

Approach
- The following arthroscopic portals are used to varying extents in the surgical treatment of disabled throwers:
  - Posterior: established first; main viewing portal
  - Anterior: main working portal: knot tying; anchor placement in anterosuperior glenoid rim
  - Posterolateral ("portal of Wilmington"): anchor placement in the posterosuperior glenoid; passage of sutures through the posterosuperior labrum. No cannulas are used in this percutaneous portal. Only small-diameter anchor insertion devices and suture passers are used to minimize injury to the cuff musculature because this portal traverses the muscular portion of the posterosuperior rotator cuff.
  - Anterosuperior: accessory portal added depending on the nature of the intra-articular pathology; may be used to view the anteroinferior labrum and capsule, or to assist in shuttling sutures through the anteroinferior capsule

## ESTABLISHING PORTALS
- The posterior portal is established by identifying the posterolateral acromial border and making a 5-mm skin incision about 2 cm medial and 2 to 3 cm inferior to the posterior corner of the acromion in the palpated soft spot between the infraspinatus and teres minor portions of the rotator cuff.
  - A blunt trocar is directed from this incision anteriorly with gentle pressure to palpate the space between the rounded humeral head laterally and the glenoid rim medially.
  - The coracoid process is palpated with the opposite index finger and is used as a guide to direct the trocar to the correct plane into the glenohumeral joint.
- The remaining portals are established after arthroscopic examination of the joint using an "outside-in" technique with an 18-gauge spinal needle.
  - The spinal needle creates minimal soft tissue trauma, and multiple passes can be made as needed to determine the proper location of secondary portals to yield unimpeded trajectories to areas of the joint requiring repair (TECH FIG 1).

## DIAGNOSTIC ARTHROSCOPY
- The joint is systematically inspected to ensure that all areas are examined and no pathology is overlooked.
  - Areas requiring particular attention in disabled throwers include superior labrum and biceps anchor, rotator cuff insertion, posterior capsule and recess, and anteroinferior labrum and capsule.
- We routinely perform provocative tests to assess both superior labral integrity and overall stability in the joint.
  - Peel-back test: The posterosuperior labrum is assessed dynamically for evidence of instability in the abducted and externally rotated position (late cocking position). The arm is released from traction and is brought into the full cocking position; an unstable labrum will fall off the glenoid rim and shift medially along the glenoid neck (TECH FIG 2A–D).
  - Drive-through test: Normally, intact capsular and labral restraints appose the humeral head into the glenoid such that easy passage of the arthroscope from posterior to anterior at the midpoint of the glenoid or sweeping of the scope from superior to inferior along the anterior glenoid rim is not possible. When these maneuvers are possible, they are nonspecific evidence of disruption of the labrum or capsular ligaments according to the “circle concept” of glenohumeral stability.3,9
Fraying and disruption of superior labral fibers inserting into the glenoid
Adjacent irritation of the capsule (TECH FIG 2F)
Disruption of the smooth contour of the articular cartilage at the glenoid rim
Superior labral sulcus more than 5 mm or a biceps root that can be displaced medially along the glenoid neck

INTRA-ARTICULAR DÉBRIDEMENT

- A full-radius motorized shaver (Stryker Endoscopy, San Jose, CA) is used to gently remove frayed or flaplike tissue and loose debris from the joint.
- Careful control of suction pressure on the shaver will ensure that only loose tissue is removed and the bulk of the repairable labrum is retained.

SUPERIOR LABRAL REPAIR

Site Preparation

- We briefly outline our steps for SLAP repair because they may differ slightly from elsewhere in this text.
- Regardless of the specific techniques used, the goal is secure fixation of the biceps anchor to the glenoid rim and obliteration of the peel-back phenomenon.
- An arthroscopic rasp (Arthrex, Naples, FL) is used to separate any loose attachments of the labrum to the glenoid rim to mobilize the lesion and free it from medialized scar (similar to a medialized Bankart lesion).
- A rasp is preferred over a sharp elevator, which can skive and injure normal labral tissue.
A spinal needle is used to locate this portal to allow proper insertion angle for anchor placement in the glenoid rim at 45 degrees relative to the glenoid face to ensure secure fixation in bone and prevent skiving under the glenoid articular cartilage or along the glenoid neck (TECH FIG 4B).

A 4-mm skin incision is made and the Spear guide (3.5 mm; Arthrex) with sharp trocar is used to pierce the muscular portion of the posterior rotator cuff as it is advanced into the joint.

Penetration of the Spear guide is done under direct arthroscopic visualization to ensure that the guide enters the joint medial to the rotator cable, which marks the intra-articular location of the musculotendinous junction of the rotator cuff (TECH FIG 4C). Because of its small diameter and passage in the muscular portion of the cuff, there is minimal iatrogenic injury with this approach.

The sharp trocar is removed, and the Spear guide is brought immediately onto the glenoid rim adjacent to the previously prepared bone bed and held firmly in the proper orientation as described above (TECH FIG 4D).

An assistant passes the power drill into the guide and carefully advances the drill bit to the hilt.

Position of the Spear guide is carefully maintained as the drill is removed and the anchor is introduced in the guide and tapped into a fully seated position in the bone.

We insert these anchors to the hilt of the handle of the insertion device.

Gentle twisting inline with the anchor is often needed to remove it in dense bone.

Alternatively, gentle tapping with a mallet inline can be used to remove the inserter.

The Spear guide is removed and the anchor fixation is tested with gentle pulling on the sutures (TECH FIG 4E).

**Suture Passage**

Both suture limbs are brought out the anterior cannula using a looped suture retriever (Arthrex) (TECH FIG 5A).

The medial suture (closest to labrum) is designated for passage through the labrum.
A small-diameter suture-passer device with a retrievable wire loop (Lasso SuturePasser; Arthrex) is used to shuttle the suture through the labrum.

- The suture-passer device is brought into the joint via the same incision and trajectory as the Spear guide (TECH FIG 5B).
- It is used to pierce the labrum from superior to inferior at the location of the anchor to achieve a solid bite of labral tissue (TECH FIG 5C).

- The wire loop is advanced over the glenoid rim and retrieved through the anterior portal (TECH FIG 5D).
- The previously identified suture is threaded into the loop and the suture-passer device is gently removed from the portal of Wilmington while shuttling the “post-limb” suture through the superior labrum.
- Suture passage is done slowly and under visualization so that tangles may be identified and corrected from the anterior portal using the suture retriever (TECH FIG 5E,F).

**TECH FIG 4 • (continued)**

D. Spear guide is carefully positioned on the glenoid rim and held firmly in place during drilling and anchor insertion. Proper insertion angle (45 degrees to the glenoid face) is critical for firm fixation of the suture anchor in bone. E. Spear guide is removed. The suture anchor has been fully inserted in the glenoid rim, and fixation is tested with a steady pull on the sutures. (In this image, the anchor has been rethreaded with no. 1 PDS suture before the start of the case [see text]).

**TECH FIG 5 • A.** Both suture limbs are retrieved through the anterosuperior portal. In this image, the suture anchor has been used with the FiberWire suture that the anchor is normally packaged with (see text). B. The suture-passing device is brought into the joint through the same trajectory as the Spear guide in the previous steps, minimizing the risk of inadvertent damage to the rotator cuff and capsule. C. The suture-passing device is advanced through the superior labrum from superior to inferior to capture the bulk of the labrum and is carefully advanced over the glenoid rim to prevent damage to the articular surface. The wire loop is advanced for retrieval from the anterosuperior portal. D. The wire loop is retrieved from the anterosuperior portal using a gated suture retriever. The previously identified “post-limb” suture (the suture closest to the labrum as they exit the fully seated anchor) is threaded into the wire loop. The suture-passing device and wire loop are then carefully withdrawn out the portal of Wilmington, shuttling the “post-limb” suture through the labrum. E. Passing suture limbs slowly allows for identification of suture tangling, which may occur during suture passage through the labrum. F. Slack sutures are easily untangled using a gated suture retriever to identify and untangle sutures from the anterosuperior portal. (continued)
The extent of capsular plication is subjective. The goal is to obliterate redundant capsule by placing sutures sequentially from inferior to superior to eliminate anterior instability while preventing inadvertent restriction to full external rotation (TECH FIG 7A,B).

The above steps are repeated as needed for additional posterior anchors in the superior labrum.

Anterosuperior Repair

Anterosuperior anchors are placed through the anterior cannula with the same orientation concerns and technique as described for posterior anchors.

Anterior suture limbs are passed and retrieved through the same anchor, which can create tangling of sutures. In addition, given the orientation of passage and retrieval of anterior sutures through the anterior cannula, a “sawing” effect can be created as the suture is drawn through the tissue, which may damage the anterosuperior labrum.

To minimize this risk, we use a tissue-penetrating device with a gated suture-retriever loop (eg, BirdBeak; Arthrex) to retrieve the post-limb suture through the anterosuperior labrum.

Dynamic Assessment of Repair

Peel-back test: The peel-back phenomenon should be obliterated and the labrum should remain firmly fixed to the superior glenoid during full cocking of the arm (TECH FIG 6).

Drive-through test: Advancement through the joint at mid-glenoid should not be possible after SLAP repair; if this test continues to be positive, then additional anteroinferior capsular redundancy is likely (see below).

MINI-Plication OF THE ANTERIOR CAPSule

The extent of capsular plication is subjective. The goal is to obliterate redundant capsule by placing sutures sequentially from inferior to superior to eliminate anterior instability while preventing inadvertent restriction to full external rotation (TECH FIG 7A,B).

A rasp or “whisker” shaver (Arthrex) is used to abrade the capsule to aid in healing of the plication (TECH FIG 7C,D).

no. 1 PDS sutures are placed beginning anteroinferiorly with pointed suture advancement instruments of varying curvatures (Spectrum; Linvatec, Key Largo, FL).

A “bite” capsule is taken laterally and advanced and sutured to the anteroinferior labrum, obliterating a redundant anterior recess (TECH FIG 7E,F).

Placement of sequential sutures allows for repeat examination to ensure anterior stability is restored without creating motion restriction (TECH FIG 7G).

Rarely, a discrete anteroinferior labral avulsion from the glenoid is present that is repaired as described elsewhere in the text. This is most easily accomplished before superior labral repair.

An additional anteroinferior portal may be required to achieve an appropriate anchor insertion angle onto the glenoid rim and to ease suture passage and management.
TECH FIG 7 • A. Multiple anterior plication sutures are used to obliterate redundant anteroinferior capsular tissue. B. Diagram in axial orientation to the glenoid showing accordion-like plication and shortening of the anterior capsule as it is sutured to the labrum. C. An arthroscopic rasp is used through the anterosuperior portal to abrade the capsular tissue and generate a healing response in the tissue after plication. D. Anterior capsule after abrasion and before suture placement. E. Starting anteroinferiorly, a pointed suture-passing device is used to suture a bite of lateral capsule to the labrum, as shown in F. As the knot is tied, this suture effectively shortens and reduces the anterior capsule. G. Multiple no. 1 PDS anteroinferior capsular plication sutures after tying of the final and most superior plication stitch.
POSTEROINFERIOR CAPSULOTOMY

- As stated earlier, a posterior capsulotomy is indicated only in patients unable to attain a GIRD of less than 20 degrees to allow restoration of full motion and normal glenohumeral biomechanics (TECH FIG 8A).
- Arthroscopic findings in these recalcitrant cases include inferior recess restriction and a thickened PIGHL (more than 6 mm thick).
- Two techniques can be used:
  - Arthroscope in anterior portal and instrumentation in standard posterior portal
  - Arthroscope in standard posterior portal and instrumentation in portal of Wilmington. We prefer this method because it allows more direct visualization of the capsular tissue as it is released (TECH FIG 8B). A small-diameter cannula (5.5 mm) may be needed to allow easy passage of the cautery through the portal of Wilmington.
- A hooked-tip arthroscopic electrocautery with long shaft (Meniscal Bovie; Linvatec) is used to create a full-thickness capsulotomy from the 6 o’clock to the 3 or 9 o’clock position in the posteroinferior quadrant.
- The capsulotomy is made approximately a quarter-inch from the labrum.
- Gentle sweeping motions are used to successively divide tissue under direct visualization (TECH FIG 8C-E).
- It is critical to perform the procedure without chemical paralysis induced by the anesthesia staff.
- Muscular twitching will alert the surgeon that the electrocautery is too close to the axillary nerve and causing injury.
- If this occurs, the capsulotomy should be shifted to a more superior and medial position or abandoned altogether if no safe zone is found.
- Posteroinferior capsulotomy typically results in a 50- to 60-degree increase in internal rotation immediately postoperatively.

**TECH FIG 8**

A. Location of the posteroinferior quadrant capsulotomy. B. Intraoperative view showing the instrument placement for posteroinferior quadrant capsulotomy. The arthroscope is in the standard posterior viewing portal and the cautery is in the portal of Wilmington. A small-diameter cannula (5.5 mm) may be required for passage of the hook-tipped cautery device through the portal of Wilmington. C. View of the posteroinferior capsule showing thickening and restriction of the inferior recess. D. The hook-tipped cautery is used to successively divide the capsule about 3 to 5 mm from the labrum under direct visualization. E. Completed capsulotomy. Muscle fibers just posterior to the capsule are visible between the divided edges of the capsule.
POSTOPERATIVE CARE

Follow-up
- Procedures are performed on an outpatient basis.
- Return for dressing change postoperative day 1.
- Ice or cooling pad is encouraged for first 48 hours.
- Sutures are removed at 1 week.
- Starting at 1 week, self-directed range-of-motion exercises are begun under specific guidelines (see below). Patients are seen regularly to assess progress and modify rehabilitation as needed.

Rehabilitation Time Table
- Immediate
  - Passive external rotation with arm at side (not abduction) within specific parameters
  - Elbow flexion and extension
  - Capsulotomy patients are started on “sleeper” stretches on postoperative day 1.
- Weeks 1 to 3
  - Pendulum exercises
  - Passive range of motion using pulley device in forward flexion and abduction to 90 degrees only
  - Start shoulder shrugs and scapular retraction exercises in sling.
  - Sling should be worn when not out for exercises.
- Weeks 3 to 6
  - Sling is discontinued at 3 weeks.
  - Passive range of motion is advanced to full motion in forward flexion and abduction.
  - “Sleeper” stretches are started in patients not having capsulotomy.
- Weeks 6 to 16
  - Stretching and flexibility exercises are continued.
  - Passive external rotation stretching in 90 degrees of abduction is begun.
  - Strengthening for rotator cuff, scapular stabilizers, and deltoit is started at 6 weeks.
  - Biceps strengthening is delayed until 8 weeks.
  - Daily “sleeper” stretches are continued.
- 4 months
  - Interval throwing program on level surface
  - Stretching and strengthening is continued (internal rotation stretches are emphasized).
- 6 months
  - Pitchers begin throwing full speed depending on pain-free progression through interval throwing program.
  - Continue daily internal rotation stretches.
- 7 months
  - Full-velocity throwing from mound
  - “Sleeper” stretches and scapular conditioning are
performed daily indefinitely while the patient continues throwing competitively.

OUTCOMES

- SLAP repair in high-level throwers: 182 pitchers treated over 8 years (one third professional, one third college, one third high school)\(^2\)
  - 92% returned to premorbid performance or better.
  - Average UCLA score was 92% excellent at 1 year and 87% excellent at 3 years.
- 164 pitchers undergoing SLAP repair and posteroinferior capsular stretching:
  - Average GIRD = 46 degrees preoperatively, 15 degrees at 2 years
  - Eight pitchers undergoing SLAP repair and posteroinferior quadrant capsulotomy:
    - Average GIRD = 42 degrees preoperatively, 12 degrees at 2 years
    - Average fastball velocity = 11-mph increase at 1 year

COMPLICATIONS

- Similar to other arthroscopic shoulder reconstructions: rare incidence of infection; failed repair; painful adhesion formation; subacromial irritation; stiffness
- Physicians and therapists must be vigilant about development of postoperative stiffness in overhead athletes. Stiffness can be addressed effectively with modification of the rehabilitation program if it is identified early with regular follow-up and directed therapy.

1. Burkhart SS. Arthroscopically-observed dynamic pathoanatomy in the Jobe relocation test. Presented at Symposium on SLAP Lesions. 18th Open Meeting of the American Shoulder and Elbow Surgeons, Dallas, TX, Feb. 16, 2002.
DEFINITION
- The long head of the biceps tendon has long been recognized as a potential source of pain and cause of shoulder impairment.\(^1\),\(^{19,20,33}\)
- Although biceps tendon pathology can occur in isolation, it more frequently occurs concomitantly with rotator cuff disease, and its neglect may account for a subset of patients who fail to respond to rotator cuff repair.
- Pathology of the long head of the biceps tendon presents in a spectrum from subtle tendinopathy observed on diagnostic imaging studies to frank tearing or subluxation appreciated intraoperatively.
- Because the functional significance of the biceps tendon long head has been the subject of considerable debate, treatment has often been tailored more to patient symptoms, activity levels, and expectations rather than strict operative criteria.
- The ideal indications and optimal operative technique remain controversial, although recent advances in arthroscopic technology have led to an evolution of surgical strategies.

ANATOMY
- The long head of the biceps brachii originates from the supraglenoid tubercle and the superior aspect of the glenoid labrum.
- Multiple anatomic variants of the long head biceps tendon origin have been described, the most common of which involves an equal contribution from the anterior and posterior labrum.\(^{32}\)
- The tendon travels intra-articularly (but extrasynovially) an average of 35 ± 5 mm toward the intertubercular (bicipital) groove between the greater and lesser tuberosities.\(^{28}\)
- The mean tendon length is 9.2 cm, with greatest width at its origin (about 8.5 × 7.8 mm).\(^{23}\)
- At the site of intra-articular exit lies the annular reflection or biceps pulley, whose fibers are derived from the superior glenohumeral, the coracohumeral ligament, and the superficial or anterior aspect of the subscapularis tendon (FIG 1). Externally this structure’s counterpart is the transverse humeral ligament.
- The bicipital groove has been a topic of significant study in the literature for its relevance to arthroplasty and it has been implicated as a contributing factor to tendinopathy involving the long head of the biceps.\(^{6,26}\)
- The dimensions of the bicipital groove vary along its mean 5-cm length. At its entrance, the width ranges from 9 to 12 mm, and the depth is about 2.2 mm. In its midportion, the groove narrows to a mean width of 6.2 mm and depth of about 2.4 mm, which may contribute to the entrapment of a hypertrophic intra-articular component; this has been referred to as the “hourglass biceps.”\(^{6,15,26}\)
- The bicipital groove internally rotates from proximal to distal with a mean change in rotation of the lateral lip estimated at about 16 degrees.\(^{15}\)
- The biomechanical significance of the biceps tendon long head is controversial. Some authors have advocated a role of the long head of the biceps in contributing to shoulder stability in overhead athletes.\(^{12,22}\) Other authors, in separate studies,
have used electromyographic analysis to conclude that the long head of the biceps tendon does not contribute to shoulder stability.\(^{18,36}\)

- The extent of functional loss of supination and elbow flexion strength after biceps tenotomy has not been clearly established and is a source of controversy in the literature but may be estimated at 10%.\(^{34}\)

**PATHOGENESIS**

- Long head of biceps tendinopathy encompasses a spectrum of pathology, including intratendinous signal change, synovitis of the sheath, partial tearing, and frank tendon rupture (FIG 2).
- The etiology of long head biceps tendinopathy is thought to be multifactorial.
- Identifiable causes include degenerative changes (usually in association with rotator cuff disease),\(^{19,33,34}\) degenerative osteophyte spurring and stenosis within the bicipital groove,\(^{6,26}\) inflammatory disease, traumatic injury, lesions of the biceps pulley complex or subscapularis tendon, and subtle forms of glenohumeral instability or superior labral anterior posterior (SLAP) tears.
- Lesions of the pulley complex (which contributes to stability of the tendon within the intertubercular groove) or tears of the upper subscapularis tendon may permit intra-articular subluxation and mechanical symptoms.
- “Hidden” cuff tears within the rotator interval or compromise of the annular reflection pulley may permit extra-articular long head biceps subluxation, which can lead to pathologic changes to the long head biceps tendon.
- Tears of the superior labrum such as type II SLAP tears and more subtle patterns of instability such as the peel-back mechanism in throwing athletes can also cause bicipital tendinopathy.

**NATURAL HISTORY**

- Little is known about the natural history of biceps tendinopathy, so prediction of a patient’s clinical course is difficult.
- Patients with high-grade tendinopathy, either in isolation or in association with cuff tears, seem to be at risk of subsequent rupture.
- Spontaneous rupture often alleviates the chronic pain preceding the event.\(^{34}\)

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- As for bicipital tendinopathy, patients’ historical presentations vary.
  - Patients may complain of anterior shoulder pain exacerbated by resisted elbow flexion and supination.
  - The history and character of shoulder pain is less helpful in making the diagnosis than the appropriate physical examination and diagnostic imaging findings in a relevant context.
  - Biceps tendon disorders can present either in isolation or in association with other pathology, typically tears of the rotator cuff.
  - Pain due to biceps pathology is often referred to the bicipital groove area.
  - Physical examination findings are variable but typically include focal tenderness to palpation over the course of the biceps long head in the bicipital groove.
  - Examinations and tests to perform include:
    - Speed’s test: low sensitivity and specificity (estimated 32% to 68% and 56% to 75%); may be indicative of biceps tendinopathy in appropriate clinical setting
    - Yergason’s test: A positive result suggests biceps tendinopathy in the appropriate clinical context.
    - Active compression test: Primarily assists in differentiating between symptomatic superior labral pathology and acromioclavicular joint pathology. A positive result may suggest biceps tendinopathy in the appropriate clinical context.
  - Despite these recommendations, few studies have corroborated the sensitivity, reliability, or accuracy of these findings.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Magnetic resonance imaging (MRI) and ultrasound are the primary methods by which biceps tendinopathy is diagnosed.
  - For the diagnosis of subluxation or dislocation of the long head of the biceps, ultrasound has a reported sensitivity of 96% to 100% and specificity of 100%.\(^2\) For the assessment of complete rupture or the determination of a normal tendon, ultrasound has a sensitivity of 50% to 75% and specificity of 100%. Ultrasound is most useful to demonstrate pathology in the intertubercular groove and has been shown to be highly operator-dependent.
  - MRI can identify intratendinous tendon abnormality, bicipital sheath hypertrophy, concomitant superior labral and rotator cuff pathology, the intra-articular course of the tendon, and the relationship of the biceps to the structures of the annular reflection pulley that stabilize it (FIG 3).

**DIFFERENTIAL DIAGNOSIS**

- Long head biceps brachii tendinitis or tenosynovitis
- Long head biceps brachii partial tear
- Long head biceps brachii rupture
- Long head biceps brachii instability or subluxation
Chapter 7  ARTHROSCOPIC TREATMENT OF BICEPS TENDONOPATHY

- SLAP tear
- Acromioclavicular joint pathology
- Anterosuperior rotator cuff tear
- Subcoracoid impingement
- Subscapularis pathology

NONOPERATIVE MANAGEMENT

- Treatment of biceps tendinopathy depends in part on whether it presents in isolation as a primary problem or is associated with other pathology.
- Alternative nonoperative management of suspected biceps pathology includes activity modification, a course of nonsteroidal anti-inflammatory medication, and corticosteroid injections targeted directly into the biceps sheath within the intertubercular groove. Such an injection can be both therapeutic and diagnostic. With respect to tendon involvement, nonscientific relative surgical indications include symptomatic partial-thickness tearing or fraying greater than 25% to 50% of its diameter, or tendon subluxation or dislocation from its normal position within the bicipital groove.
- Patient factors influencing treatment include the patient’s age and activity level, occupation, desired recreational activities, and expectations.
- Because the biceps tendon is a known “pain generator,” its evaluation and inclusion in treatment of cuff disorders is particularly important.
- Preoperative consideration must be given to anticipate operative strategies if encountered.
- Operative alternatives in treating biceps tendon disorders include débridement, tenolysis (release of the biceps tendon long head), and tenodesis, in which the biceps is reattached to either bone or soft tissue of the proximal humerus. Each has advantages and disadvantages (Table 1).

SURGICAL MANAGEMENT

- Surgical decision making includes patient factors, biceps tendon structural compromise, and concomitant shoulder pathology.
- With respect to tendon involvement, nonscientific relative surgical indications include symptomatic partial-thickness tearing or fraying greater than 25% to 50% of its diameter, or tendon subluxation or dislocation from its normal position within the bicipital groove.
- Patient factors influencing treatment include the patient’s age and activity level, occupation, desired recreational activities, and expectations.
- Because the biceps tendon is a known “pain generator,” its evaluation and inclusion in treatment of cuff disorders is particularly important.
- Preoperative consideration must be given to anticipate operative strategies if encountered.
- Operative alternatives in treating biceps tendon disorders include débridement, tenolysis (release of the biceps tendon long head), and tenodesis, in which the biceps is reattached to either bone or soft tissue of the proximal humerus. Each has advantages and disadvantages (Table 1).

The selected surgical approach should take into consideration patient factors, intraoperative findings, and surgeon preference and comfort.

- Patient factors include age, work, recreational and activity demands, expectations, and perspective on influence of cosmesis.
- Intraoperative findings influence decision making in a number of ways, including bone quality, soft tissue quality, the presence of injury to the biceps sling or subscapularis, and the presence of instability.
- Surgeon factors include arthroscopic proficiency and experience and concomitant surgical procedures that may influence the treatment approach (eg, swelling in the subacromial space during concomitant arthroscopic rotator cuff repair).

Few studies have compared surgical alternatives within the same population of patients. Most such comparative studies

Preoperative Planning

Clinical evaluation to determine the contribution of the biceps tendon to patient symptoms is an important component of decision making and helps when encountering biceps pathology.

Examinations for cuff pathology, particularly in the rotator interval (“hidden lesions” of the cuff) and for subscapularis integrity (belly press or lift-off test) are necessary components of the preoperative workup.

Accurate preoperative evaluation should include appropriate radiographs to assess bicipital and acromial (outlet view) morphology.

The bicipital groove view permits assessment of groove depth and the presence of osteophytes but may be unnecessary given the typical quality of routine axial MR images.

MR images can be viewed to assess for biceps continuity (sagittal and coronal views) and intratendinous signal change (axial views) as well as tendon subluxation (axial and coronal views).

Attention must be paid when examining MR films to evaluate the appearance of the adjacent subscapularis, whose upper border is an important restraint against inferior biceps subluxation.

Positioning

Positioning is a matter of surgeon preference.

When biceps tendon pathology is perceived to be isolated or a significant component of the patient’s presentation, we have found that beach-chair positioning affords optimal orientation.

Biceps tenodesis or tenolysis can also be easily performed in the lateral decubitus position.

All bony prominences are carefully padded and the neck is maintained in a neutral position, ensuring adequate circumferential exposure to the scapula (posteriorly) and medial to the coracoid (anteriorly).

Alternatively, depending on surgeon preference, the patient may be placed in the lateral position.

Approach

Standard arthroscopic portals for this procedure include the posterolateral portal for initial viewing, an anterior “operative” rotator interval portal, and the direct lateral subacromial portal (operative and viewing).

Additional accessory portals within the antero-supero-lateral aspect of the rotator interval may facilitate work in the subdeltoïd space during tenodesis.

On initial arthroscopic examination, the biceps is carefully inspected along its course from the posterosuperior glenoid labral attachment to its exit within the bicipital sheath.

Examination should include both visualization along the course and down the sheath (enhanced by use of a 70-degree lens) and palpation.

Because only a portion of the biceps tendon long head is visualized within the joint, the biceps tendon must be translated into the joint using a probe, switching stick, or some tissue-safe tool. This enhances the surgeon’s ability to visualize tendinopathic changes that may otherwise go unrecognized.

Meticulous examination of the proximate annular reflection pulley and subscapularis tendon insertion is obligatory.

Biceps long head abnormalities can include:

- Hyperemia, seen in patients with adhesive capsulitis or in biceps instability
- Overt subluxation: Most commonly subluxation is inferior due to injury to its inferior restraints, composed of the upper subscapularis tendon, or bicipital sling, composed of...
the intra-articular extension of the coracoacromial and coracohumeral ligaments.
- Subtle subluxation: Some authors have described a subtle instability pattern in which biceps tendon excursion within the otherwise normal-appearing sheath is greater than normal and deserves “stabilization.”
- Biceps “incarceration”: Some authors advocate the arthroscopic active compression test to assess for this uncommon entity. This test is performed intraoperatively with the arm positioned in forward elevation, slight adduction, and internal rotation.

**BONY TENODESIS**

**Arthroscopic Interference Screws**

- Before release at the superior labral attachment, the biceps long head must be controlled.
  - This is best achieved by the securing suture about 1 to 2 cm distal to the attachment.
  - This can be done either via spinal needle and PDS percutaneously, or by suture passage using a variety of available suture-shuttling instruments.
- The biceps tendon attachment is then released at the anterosuperior glenoid using a bipolar cautery, arthroscopic scissors or basket, or retractable knife.
- The suture tagging the long head of the biceps tendon is then retrieved though an anterior skin incision just outside the arthroscopic cannula and secured with a Kelly clamp.
- The arthroscope is redirected into the subacromial space. Using the direct lateral portal, an arthroscopic bursectomy facilitates adequate visualization within the subdeltoid space and selection of the site of tenodesis.
- Visualization of the anterosuperior proximal humerus in the subdeltoid space may be facilitated by placing the traditional lateral portal slightly more anteriorly, as advocated by Romeo et al.29
  - With the camera repositioned in this lateral portal, the long head of the biceps tendon is identified in the sheath within the intertubercular groove (just lateral to the lesser tuberosity); this can be facilitated by a spinal needle.
- Using the small incision through which the biceps has been retrieved, the bicapital sheath is incised with an arthroscopic scissors, electrocautery device, or retractable arthroscopic knife.
- The release is performed along the lateral aspect of the sheath to minimize any risk to the subscapularis tendon’s insertion.
- The release should also be deep enough only to visualize the groove and tendon within it, because the ascending branch of the anterior humeral circumflex artery (the primary blood supply to the humeral head) lies beneath.
- This incision in the bicipital sheath is carried proximally to the lateral aspect of the rotator interval and the tendon is then retrieved through either the anterior or accessory anterolateral portal and secured with a clamp.
- The proximal end of the tendon is then resected after first placing a nonabsorbable whipstitch just distal to the site of intended tenotomy.
  - Because the interference screw can cause fraying of conventional first-generation sutures, the whipstitch is better composed of a newer second-generation material such as FiberWire or Herculine.
  - The suture should be placed 10 to 20 mm distal to the exposed proximal portion, depending on how much diseased tendon is present, how much was resected intraoperatively, and the intended location of the tenodesis.
  - When using an interference screw, the surgeon must ensure that the length of the suture is sufficient to pass through the cannulated interference screwdriver (TECH FIG 1).
  - Attention to suture management by use of cannulas is critical at this point. They ensure optimal visualization and soft tissue and suture management and minimize iatrogenic trauma to adjacent soft tissues.
- A guidewire for the tenodesis screw is driven into the intertubercular groove about 15 mm distal to the superior aspect of the groove (at the leading edge of the supraspinatus insertion).29 The guidewire is inserted perpendicular to the groove to a depth of 30 mm.
- The scope is repositioned within the lateral (or most anterior lateral) portal and a cannulated 8-mm reamer is drilled to a depth of about 30 mm under direct arthroscopic visualization.
- The guidewire is removed and a screw is selected for tenodesis. Usually an 8-mm bioabsorbable implant is chosen, but this varies depending on bone quality.
- The proximal tendon is then retrieved with its previously placed whipstitch from the subdeltoid space out through the anterolateral portal.
- One limb of the whipstitch is loaded to the tenodesis screwdriver, and the bioabsorbable screw is loaded.
- The suture limb within the screwdriver is secured with a clamp at the top of the driver, thereby fixing the tendon at the tip of the insertion device for delivery to the base of the tunnel.
- The tendon and driver are inserted the full depth of the tunnel, and the interference screw is advanced while maintaining the driver position and suture tension. It should be advanced such that it is flush with the cortical surface of the intertubercular groove.
- The two remaining suture limbs (one exiting the cannulated screw, the other trailing between the screw and the bone tunnel) are arthroscopically tied on the top of the interference screw, providing further reinforcement.
- The arthroscopic portals and subacromial space are irrigated thoroughly and injected with local anesthetic with epinephrine.

**Arthroscopic Suture Anchors**

- Before being released at the superior labral attachment, the biceps long head must be controlled. This is best achieved by securing the suture about 1 to 2 cm distal to the attachment.
An alternative technique involves an intra-articular tenodesis. Advantages include the ability to perform the procedure without requiring movement of the scope from the joint to the subacromial space, or subacromial bursectomy.

- In this procedure, a stay suture is placed at the origin of the biceps sheath just at the anterior margin of the supraspinatus.
- Flexion of the shoulder and use of a 70-degree lens facilitate identification of the most superior aspect of the bicipital groove. This will be the site of tenodesis.
- The biceps tendon is released from its origin, with the stay sutures percutaneous (at the site of spinal needle penetration).
- The anterosuperior portal is used to target the proximal humeral tenodesis site, generating a healing response along the proximal centimeter of the bicipital groove. By rotating and flexing the shoulder, the biceps tendon can be translated to permit good visualization of the tenodesis site and to facilitate subsequent targeting for anchor placement.
- Several alternative fixation techniques exist, the most common of which is anchor insertion, followed by suture passage and knot tying through the proximal tendon stump.
- Alternatively, the surgeon may make multiple passes through the biceps tendon (using a locking stitch of nonabsorbable suture such as FiberWire) and then use a knotless-type anchor (such as the Arthrex “push-lock” or “swivel-lock”) to perform a secure tenodesis in a percutaneous fashion over a previously placed small-diameter cannula. This latter technique is particular good in cases with cuff tears, in which the proximal bicipital groove is so readily accessible.
Arthroscopic Fixation

This technique, in which the biceps tendon is secured to the soft tissues in the rotator interval, is based on the percutaneous intra-articular transtendon (PITT) technique described by Sekiya and Rodosky (TECH FIG 3).

A spinal needle is placed percutaneously through the lateral aspect of the rotator interval proximate to the annular reflection pulley and then through the biceps tendon, about 1 to 2 cm distal to its supraglenoid origin.

TECH FIG 2 • Arthroscopic images showing intra-articular tenodesis of the long head of the biceps tendon at the proximal aspect of the bicipital groove. A. Anchor placement. B. Suture passage. C. Knot tying. D. Completed tenodesis.

SOFT TISSUE TENODESIS

Arthroscopic Fixation

This technique, in which the biceps tendon is secured to the soft tissues in the rotator interval, is based on the percutaneous intra-articular transtendon (PITT) technique described by Sekiya and Rodosky (TECH FIG 3).

A spinal needle is placed percutaneously through the lateral aspect of the rotator interval proximate to the annular reflection pulley and then through the biceps tendon, about 1 to 2 cm distal to its supraglenoid origin.

TECH FIG 3 • Percutaneous transtendinous or soft tissue tenodesis of the long head of the biceps tendon. A. Coronal plane view of suture fixation to secure the long head of the biceps tendon to the adjacent soft tissue structures in the proximal portion of the bicipital groove. B. Sagittal view showing the fixation with the arm in forward elevation and the knots secured in the subdeltoid space.
A 0 PDS suture is then shuttled through the tendon; it is retrieved through the anterior interval portal using a grasper.

This suture is then replaced by shuttling a nonabsorbable suture (such as no. 2 FiberWire or other comparable suture).

This process is repeated 5 to 6 mm distally along the biceps tendon’s course just proximal to the superior aspect of the intertubercular groove. Ideally, this second suture is of a different color so that the first set of suture limbs can be distinguished from the second.

Next, the limb of the no. 2 nonabsorbable suture exiting the cannula is shuttled with the second PDS back through the biceps and annular reflection pulley. A mattress suture is placed in these structures. It exits the skin through two separate punctures made by the spinal needle passages.

A tenotomy is performed via the anterior interval portal using an Arthrocare wand, needle-tip Bovie, arthroscopic scissors, or up-biting narrow meniscal basket.

The intervening residual stump is excised and the arthroscope repositioned within the subacromial space, which is carefully debrided to enhance visualization and retrieval of the two suture sets.

Retrieval of the percutaneous suture pairs is facilitated with an arthroscopic “crochet hook.”

An alternative technique for retrieving hard-to-find sutures involves making a small incision directly over the percutaneous suture exit sites and loading the suture limb within a single-loop knot pusher, which is then pushed through the skin and into the cleared anterior subacromial space. The sutures are then easily identified and grasped, unloading from the knot pusher, which is withdrawn without difficulty.

Upon retrieval, which can be done one at a time, mattress sutures are tied under direct arthroscopic visualization in the anterior subacromial space.

After thorough irrigation, the joint, subacromial space, and arthroscopic portals are infiltrated with 0.25% Marcaine with epinephrine.

**ARTHROSCOPIC BICEPS TENOTOMY**

In the appropriately selected patient, the procedure is carried out by simply releasing the biceps tendon at its attachment site from a rotator interval portal while viewing from posteriorly.

The intervening segment of diseased biceps tendon (in cases of tendinopathy) can be resected.

Distal migration of the tendon can be discouraged by either leaving a residual wider portion of the diseased tendon just proximal to the proximal bicipital groove or by including a small piece of the anterior superior labrum at the time of tenotomy.

Either of these strategies may preclude the tendency for distal translation and formation of a “Popeye” muscle.

**PEARLS AND PITFALLS**

| Indications | Careful assimilation of the preoperative history, physical examination, and imaging data with the findings at surgery is essential to determine which symptomatic lesions require treatment. A thorough discussion with patients about the goals, expectations, and potential complications of tenotomy and tenodesis is a key component of obtaining successful patient-based outcomes. |
| Portal placement | The location of the rotator interval portal will greatly influence the ease with which an arthroscopic tenodesis can be performed. If the initial portal is too medial, establishing an accessory anterolateral portal over the intertubercular groove about 2 cm distal and 1 cm medial to the anterolateral aspect of the acromion will facilitate instrument passage and visualization. The location of the direct lateral portal along the anterior half of the acromion in the sagittal plane will aid in visualization when working in the subacromial space. Portal placement can be optimized by localization and triangulation using a spinal needle. |
| Diagnostic arthroscopy | A key component of the arthroscopic examination is using a probe, switching device, or other instrument to displace the intertubercular portion of the tendon into the glenohumeral joint for adequate assessment. In addition, a careful examination of the fibers of the annular reflection pulley and the subscapularis insertion is essential. When viewing from the standard posterior portal, using a 70-degree lens can enhance visualization of the proximal intertubercular groove when performing an intra-articular tenodesis. |
| Visualization | An adequate bursectomy facilitated by the use of electrocautery for hemostasis will significantly assist in visualization during arthroscopic tenodesis. Attention to accurate portal placement, fluid management (pump pressure), and procedure duration will help limit soft tissue extravasation, which can impair visualization and lead to performing the tenodesis open. |
| Arm position | Manipulating the arm in flexion and extension, as well as rotation, can help in visualization as well as anchor targeting. |
| Suture management | Careful suture management during tenodesis is key to avoid inadvertent soft tissue interposition, leading to inadequate fixation, skin dimpling, or unnecessary soft tissue dissection. |
POSTOPERATIVE CARE

- The postoperative protocols for long head biceps tendon surgery vary according to the specific technique (débridement, tenotomy, or tenodesis).
  - Often the protocol will depend on the concomitant procedures, such as rotator cuff repair, performed.
- In general, after tenotomy, sling immobilization is used for 4 to 6 weeks, with passive elbow flexion and extension as dictated by the surgeon’s preference and comfort level.
  - Forceful, active elbow flexion is prohibited for 6 weeks, by which time it is expected that the biceps tendon will have scarred into the groove or “autotenodesed” sufficiently to begin active motion.23
  - This period of protection also serves to minimize the potential for a Popeye deformity and fatigue-related cramping.
  - To further minimize the risk of distal retraction, some surgeons have described the use of a compressive wrap around the arm.
  - If too tight, however, the effect may be that of a tourniquet, leading to pain, swelling, and ecchymoses.
- After biceps tenodesis, patients are immobilized in a sling for 4 to 6 weeks, with the amount of active-assisted elbow flexion and extension dictated by surgeon preference and comfort.
  - Active elbow flexion is prohibited for about 6 to 8 weeks to allow tenodesis healing.
  - Some surgeons favor limiting the last 15 to 20 degrees of terminal extension for 4 to 6 weeks after surgery to minimize stress at the tenodesis site.
  - Active elbow flexion exercises are then slowly incorporated into the rehabilitation program after 6 to 8 weeks, with strengthening delayed until the third postoperative month.

OUTCOMES

- Outcome interpretation is challenging because of the limited number of studies and the lack of homogeneous patient populations. Surgical procedures to the biceps are typically only one component of surgically treated shoulder pathology in most studies.
- Arthroscopic tenodesis
  - Checchia et al7 reported 93% good and excellent results in 14 of 15 patients, as determined by UCLA scores, who underwent arthroscopic rotator cuff repair and transtendinous soft tissue tenodesis at a mean follow-up of 32 months.
  - Boileau et al5 reported their results of arthroscopic biceps tenodesis with interference screw fixation at mean follow-up of 17 months with a Constant score improvement from 43 preoperatively to 79 at latest follow-up ($P <0.005$).
  - The historical literature regarding biceps tenodesis defines a range of unacceptable or poor results ranging from 6% to 40%.16
  - The results of open biceps tenodesis have been variable and are summarized in Table 2. Briefly, the results of arthroscopic tenodesis to date indicate that the procedure is an effective treatment for refractory biceps tendinopathy in appropriately indicated patients and may be more favorable for patients under 60 years of age.
- Arthroscopic tenotomy
  - Outcomes of arthroscopic tenotomy suggest that in the appropriately selected patient, this procedure can reliably provide pain relief, with minimal functional limitations or functional improvement.
  - Gill et al11 in 2001 reported their results of tenotomy in 30 patients at a mean follow-up of 19 months. These patients scored an average of 82 by the American Shoulder and

</table>
Elbow Surgeons (ASES) grading scale (but no preoperative comparison data were available) and a significant reduction in pain and improvement in function. They reported 87% satisfactory results and a complication rate of 13%, including one patient with a painless cosmetic deformity, two patients with loss of overhead function and subacromial impingement, and one patient with persistent pain.

- Kelly et al13 in 1998 reported the results of 307 arthroscopic tenotomies at a mean of 2.7 years of follow-up, with 68% good to excellent results. However, 70% had a Popeye sign, and 38% of patients reported fatigue-related discomfort. They found minimal loss of elbow strength as assessed by biceps curls, and 0% loss for individuals over 60. Fatigue-related discomfort was not present in the patients over 60.

- Walch et al5 in 1998 reported the results of 54 arthroscopic tenotomies at a mean of 2.7 years of follow-up, with 68% good to excellent results. However, 70% had a Popeye sign, and 38% of patients reported fatigue-related discomfort. They found minimal loss of elbow strength as assessed by biceps curls, and 0% loss for individuals over 60. Fatigue-related discomfort was not present in the patients over 60.

- The primary complications of tenotomy are:
  - Persistent pain
  - Fatigue-related cramping
  - Cosmetic deformity in the form of a Popeye sign
  - Potential slight decrease in elbow supination and flexion strength

- The primary complications of tenodesis include persistent pain, failure of the tenodesis, and refractory tenosynovitis.

- Failure of the tenodesis to heal may result in rupture of the tendon with distal retraction. In such cases, as often occurs in patients with spontaneous biceps tendon rupture, symptoms usually resolve with time.

- One study has suggested that the quality of remaining tendon available for tenodesis can significantly affect the success of the procedure.5

- Recent evidence suggests that oral nonsteroidal anti-inflammatory medication may inhibit healing, so this may be a suboptimal postoperative analgesic option.

- The primary complications of tenotomy are:
  - Cosmetic deformity in the form of a Popeye sign
  - Fatigue-related cramping
  - Potential slight decrease in elbow supination and flexion strength

Arthroscopic Treatment of Subacromial Impingement

R. Timothy Greene and Spero G. Karas

DEFINITION

- Impingement syndrome was originally described by Neer in 1972 as a chronic impingement of the rotator cuff beneath the coracoacromial arch resulting in shoulder pain, weakness, and dysfunction.
- Repetitive microtrauma of the supraspinatus tendon’s hypovascular area causes progressive inflammation and degeneration of the tendon, resulting in tendinopathy and rotator cuff tear.
- Extrinsic compression of the rotator cuff may occur against the undersurface of the anterior third of the acromion, the coracoacromial ligament, or the acromioclavicular (AC) joint.
- In a study of cadaveric scapulae, Neer observed a characteristic ridge of proliferative spurs and excrescences on the undersurface of the anterior acromion overlying areas with evidence of rotator cuff impingement.

ANATOMY

- The scapula is a thin sheet of bone from which the coracoid, acromion, spine, and glenoid processes arise.
- The acromion, together with the coracoid process and the coracoacromial ligament, form the coracoacromial arch. The arch is a rigid structure through which the rotator cuff tendons, subacromial bursa, and humeral head must pass.
- The supraspinatus tendon is confined above by the subacromial bursa and the coracoacromial arch and below by the humeral head in an area referred to as the supraspinatus outlet. There is an average of 9 to 10 mm of space between the acromion and humerus in the supraspinatus outlet. This space is narrowed by abnormalities of the coracoacromial arch. Internal rotation or forward flexion of the arm also decreases the distance between the coracoclavicular arch and the humeral head.
- The subacromial and subdeltoid bursa overlie the supraspinatus and the humeral head. These bursae serve to cushion and lubricate the interface between the rotator cuff and the overlying acromion and AC joint. The bursa may become thick and fibrotic in response to progressive inflammation, further decreasing the volume of the subacromial space.
- The supraspinatus tendon has a watershed area of hypovascularity located 1 cm medial to the insertion of the rotator cuff. This area may predispose the supraspinatus tendon to degeneration, tendinopathy, and tears from overuse, repetitive microtrauma, or outlet impingement.

PATHOGENESIS

- Extrinsic impingement of the rotator cuff is caused by abnormalities of the coracoacromial arch, resulting in an overall decreased area for the rotator cuff tendons within the supraspinatus outlet.
- Acromial morphology most commonly accounts for narrowing of the supraspinatus outlet.
- Bigliani et al. described three types of acromial morphology: the type I acromion is flat, type II is curved, and type III is hooked. They noted that 73% of cadaver shoulders with rotator cuff tears had a type III acromion.
- A type I acromion with an increased angle of anterior inclination may cause impingement of the rotator cuff by narrowing the supraspinatus outlet.
- Other processes that narrow the supraspinatus outlet include osteophytes of the AC joint; hypertrophy of the coracoacromial ligament, or the acromioclavicular joint; clavicle, or acromion; inflammatory bursitis; calcific rotator cuff tendinitis; or a flap from a bursal-sided rotator cuff tear.

NATURAL HISTORY

- Neer classified impingement into three progressive stages:
  - Stage I impingement lesions occur initially with excessive overhead use in sports or work. A reversible process of edema and hemorrhage is found in the subacromial bursa and rotator cuff. This typically occurs in patients less than 25 years old.
  - With repeated episodes of mechanical impingement and inflammation, stage II lesions develop. The bursa may become irreversibly fibrotic and thickened, and tendinitis develops in the supraspinatus tendon. Classically, this lesion is found in patients 25 to 40 years of age.
  - As impingement progresses, stage III lesions may occur, with partial or complete tears of the rotator cuff. Biceps lesions and alterations in bone at the anterior acromion and greater tuberosity may also develop. These lesions are found almost exclusively in patients older than 40.
- Stage I and II lesions typically respond to nonoperative modalities if the offending activity is limited for a sufficient amount of time.
- Refractory stage II lesions and stage III lesions require operative intervention.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with impingement syndrome typically complain of the insidious onset of shoulder pain that primarily occurs with overhead activities. Pain is typically localized to the lateral aspect of the acromion, extending distally into the deltoid.
- Patients may experience pain at night, especially when lying on the affected side.
- Typically, patients with impingement syndrome do not complain of diminished shoulder motion.
- Physical examination methods to identify subacromial impingement include:
  - Palpation of the point of Codman: Tenderness is frequently a sign of supraspinatus tendinitis, tendinopathy, or acute tear of supraspinatus tendon.
  - Range of motion: Patients with impingement may have limited internal rotation from posterior capsular tightness. Active motion is typically more painful than passive motion, especially in the descending phase of elevation.
■ Painful abduction arc: Pain from 60 to 120 degrees (maximally at 90) suggests impingement. Patients may externally rotate at 90 to clear the greater tuberosity from the acromion and increase motion.

■ Neer’s Impingement Sign: This maneuver compresses the critical area of the supraspinatus tendon against the anterior inferior acromion, reproducing impingement pain.

■ Hawkins’ Sign: This maneuver compresses the supraspinatus tendon against the coracohumeral ligament, reproducing the pain of impingement. It has high sensitivity but low specificity.

■ Impingement test: This test has greatly improved specificity for making the diagnosis of subacromial impingement. A positive test is also a predictor of satisfactory outcome after subacromial decompression.14

■ A complete physical examination of the shoulder should be performed to evaluate for associated pathology or other processes in the differential diagnosis.

■ AC arthritis: This may be clinically asymptomatic, but an inferior AC joint osteophyte can contribute to or cause impingement syndrome. If symptomatic, tenderness may be elicited at the AC joint with palpation and the cross-arm adduction test.

■ Rotator cuff tear: The history of traumatic injury is variable. Patients complain of deep shoulder pain at night and may complain of weakness in the affected shoulder. Strength testing will evaluate for rotator cuff tear and tear size. Evaluation for supraspinatus tendon tear is performed at 90 degrees of abduction in the scapular plane with maximally pronated forearms (Jobe test). Infraspinatus and teres minor weakness is assessed with resistance of external rotation. Inability to hold an externally rotated position is indicative of a massive tear (external rotation lag sign). Weakness of the subscapularis tendon is evaluated with resisted internal rotation. Inability to lift the dorsum of the hand from the ipsilateral sacrum (lift-off test) suggests a subscapularis rupture.

■ Glenohumeral instability: Subluxating or dislocating the humeral head anteriorly, posteriorly, or inferiorly while stabilizing the scapula (load and shift test) helps confirm the diagnosis of glenohumeral instability. Throwing athletes may have a complex pattern of pathology that includes anterior laxity and posterior capsular tightness, which may result in internal impingement. Internal impingement occurs during the late cocking phase of throwing and stems from contact of the articular side of the supraspinatus on the posterosuperior glenoid rim. These patients typically have posterior pain with apprehension testing. Internal impingement must be differentiated from extrinsic outlet impingement caused by coracohumeral ligament narrowing. Although a posterior capsule contracture can predispose patients to outlet impingement, classic extrinsic outlet impingement is believed to be rare in throwing athletes.

■ Biceps pathology: Pain is typically in the anterior shoulder. Tenderness may be elicited in the area of the bicipital groove. Pain during resisted flexion of the arm with the elbow in extension and the forearm supinated (Speed’s test) indicates biceps pathology.

■ Glenohumeral arthritis: Pain is associated with movement below 90 degrees of elevation. Patients complain of pain at night. Cogwheel crepitus may be present when loading the glenohumeral joint during resisted arm abduction.

IMAGING AND OTHER DIAGNOSTIC STUDIES

■ Standard anteroposterior (AP) radiographs in internal and external rotation and a supraspinatus outlet view should be taken for the evaluation of impingement syndrome.

■ A supraspinatus or acromial outlet view is a transscapular view taken with the radiographic beam angled 15 to 20 degrees caudally (FIG 1).

■ The outlet view is the best plain radiographic technique to evaluate acromial morphology. With this information, the surgeon may accurately plan the amount of osseous resection required to convert the acromion to type I morphology.

■ Additional views or diagnostic tests may be used to further evaluate the painful shoulder.

■ Axillary lateral radiographs may be helpful in showing an os acromiale.

■ Magnetic resonance imaging, computed tomography scan, arthrography, and ultrasonography should be used for patients whose diagnosis of impingement syndrome is not completely clear from the history, physical examination, and radiographs. These other modalities will also help diagnose biceps, labral, and rotator cuff pathology.

DIFFERENTIAL DIAGNOSIS

■ Rotator cuff pathology

■ AC osteoarthritis

■ Glenohumeral instability

■ Posterior glenoid and rotator cuff (internal) impingement

■ Glenohumeral osteoarthritis

■ Biceps tendon pathology

■ Adhesive capsulitis

■ Cervical spine disease

■ Viral brachial plexopathy

■ Thoracic outlet syndrome

■ Visceral problems (eg, cholecystitis, coronary insufficiency)

■ Neoplasm of the proximal humerus or shoulder girdle

FIG 1 • Supraspinatus outlet view. This view helps the surgeon assess acromial morphology and facilitates preoperative planning for the amount of acromial resection.
NONOPERATIVE MANAGEMENT

- All patients with subacromial impingement syndrome should undergo a course of nonoperative management for 3 to 6 months. In the short term, a graduated physiotherapy program has been shown to be as effective as arthroscopic subacromial decompression.\(^5\)
- Most patients can be successfully treated within 3 to 6 months. Large retrospective studies show that about 70% of patients with impingement syndrome will respond to conservative management.\(^18\)
- The rehabilitation program should start by preventing overuse or re-injury with relative rest and activity modification. Subacromial bursal inflammation may be controlled with nonsteroidal anti-inflammatory medication, hot and cold therapy, ultrasound, and corticosteroid injection when appropriate.
- Therapy is advanced as pain and inflammation subside and is directed at regaining full range of motion and eliminating capsular contractures. In particular, posterior capsular contracture is addressed with progressive adduction and internal rotation stretching.
- As pain continues to decrease and range of motion improves, strengthening of the rotator cuff and periscapular musculature is initiated. This is achieved through progressive resistance exercises with elastic bands or free weights.
- Patients should avoid overhead weight training (military press, latissimus pulldowns) and long lever arms (straight arm lateral raises) because these maneuvers can exacerbate impingement and place undue torque on the glenohumeral joint.

SURGICAL MANAGEMENT

- Operative intervention is indicated if patients continue to have symptoms of impingement syndrome that are refractory to a progressive rehabilitation program of stretching and strengthening over a minimum 3- to 6-month period.
- If the diagnosis is not completely clear, a more extensive diagnostic workup is warranted before surgical intervention.
- The most common cause of failure for arthroscopic subacromial decompression and anterior acromioplasty is error in diagnosis.\(^1\)

Preoperative Planning

- Imaging studies are reviewed to make sure that the preoperative diagnosis is correct.
- Particular attention should be paid to acromial morphology, the status of the AC joint, and evidence of rotator cuff pathology because these disease processes often coexist.
- The preoperative supraspinatus or acromial outlet view gives the surgeon an accurate measurement of the amount of bone that must be resected from the anterior acromion to convert the acromial morphology to type I.\(^16\)
- If the AC joint has developed osteoarthritic changes, the presence of an inferior AC joint osteophyte may contribute to subacromial impingement. The presence of AC arthritis may not be clinically symptomatic; thus, coplaning of the inferior AC joint should be performed with the subacromial decompression. If the AC arthritis is symptomatic, distal clavicle resection should be performed in conjunction with subacromial decompression.
- Preoperative knowledge of a rotator cuff tear is important for surgical planning of equipment, resources, and operative time as well as patient informed consent, recovery time, and time lost from work.
- Failure to recognize associated pathology is a common source of surgical failure.
- Examination under anesthesia of the affected shoulder is done before positioning. Passive range of motion is documented. The patient should be evaluated for a posterior capsule contracture, which can exacerbate impingement symptoms. Release of the posterior capsule with manipulation or arthroscopic cautery can improve a significant posterior capsule contracture.
- Anterior and posterior glenohumeral translation is examined using a modified load and shift test. Inferior translation is evaluated with the sulcus test.

Positioning

- The patient may be positioned in the beach-chair or lateral position.
- Advantages of the beach-chair position include a more customary setup for conversion to open cases such as biceps tenodesis.
- Advantages of the lateral position include better joint distraction for concomitant intra-articular arthroscopic procedures such as labral repair.

Approach

- Standard anterior, posterior, and lateral arthroscopic shoulder portals are used to perform the diagnostic arthroscopy and subacromial decompression.
- The details of these procedures are outlined in the Techniques section.

ARTHROSCOPY

- The bony anatomy of the acromial borders, clavicle, AC joint, and coracoid process is outlined with a skin marker. The proposed site of the posterior, anterior, and lateral portals are marked (TECH FIG 1).
- The posterior portal is located 2 cm medial and 2 to 3 cm distal to the posterolateral aspect of the acromion. This is the “soft spot” in the posterior triangular region of the humeral head, glenoid, and acromion.
- The anterior portal is marked 1 cm lateral and 1 to 2 cm cephalad to the coracoid process.
- The lateral portal is marked 2 to 3 cm distal to the lateral border of the acromion at the junction of the anterior and middle thirds of the acromion.
- The portal sites are infused with a mixture of 1% lidocaine and 1:300,000 dilute epinephrine solution.
- The glenohumeral joint is infused with 50 mL of the dilute lidocaine and epinephrine solution.
- The posterior portal is established with a 5-mm skin incision and a trocar is placed into the glenohumeral joint. Return of the previously injected solution confirms intra-articular placement.
■ The trocar is removed and the arthroscope is placed. Inflow is established through the arthroscope.

■ An 18-gauge spinal needle is used to confirm the anterior portal that was marked preoperatively. A 5-mm skin incision is placed over the site of the needle entry point and a probe is placed through the anterior portal.

■ A diagnostic arthroscopy is performed. All surfaces of the glenohumeral joint, the glenoid labrum, glenohumeral ligaments, biceps tendon, rotator interval, and rotator cuff are thoroughly inspected.

■ Particular attention is paid to the presence of glenohumeral arthritis, labral pathology associated with glenohumeral instability, and rotator cuff tears because they can mimic an impingement syndrome.

**SUBACROMIAL DECOMPRESSION**

■ Twenty milliliters of 1% lidocaine and 1:300,000 diluted epinephrine are injected into the subacromial space before intra-articular diagnostic arthroscopy.

■ A blunt trocar is used to redirect the posterior portal from the intra-articular position to the subacromial space. The correct position is confirmed by palpating the hard undersurface of the acromion with the trocar tip.

■ Once the trocar is felt to be in the subacromial space, it is swept laterally through the subdeltoid bursa to open the subacromial space. Care should be taken to avoid sweeping the trocar medial to the AC joint, which could injure the acromial branch of the thoracoacromial artery.

■ The arthroscope is introduced and an initial assessment of the subacromial bursa and acromial spur is done.

■ A 5-mm skin incision is used to establish the lateral portal 2 to 3 cm distal to the midlateral border of the acromion.

■ A 5.5-mm full-radius resector is introduced through the lateral portal.

■ Visualization is often difficult because of the thickened and inflamed subacromial bursa. Therefore, tri-angulation of the arthroscope and full-radius resector must be done by palpation.

■ Bursectomy cannot be initiated until the cutting flutes of the resector are visualized.

■ The tip of the anterolateral aspect of the acromion is palpated with the resector to confirm the correct subacromial orientation. Bursal resection is completed in an anterio-to-posterior and lateral-to-medial direction (TECH FIG 2A). Care must be taken not to resect the highly vascular bursal tissue medial to the musculotendinous junction of the rotator cuff.

■ A radiofrequency electrocautery device is used to coagulate any bleeding and remove the remaining soft tissue from the undersurface of the acromion, starting at the anterolateral corner of the acromion (TECH FIG 2B).

■ The electrocautery device is used to peel the coracoacromial ligament from the undersurface of the acromion and completely excise the remaining ligament stump. A complete resection of the coracoacromial ligament is confirmed when the undersurface of the deltoid is visualized as it drapes over the acromial edge (TECH FIG 2C).

**TECH FIG 1** • Acromioclavicular anatomy is outlined and the portal sites are marked.

**TECH FIG 2** • A. Arthroscopic bursectomy. The bursa overlying the tendinous portion of the rotator cuff must be thoroughly resected to evaluate the tendons for bursal-side rotator cuff tear. B. Soft tissue on the undersurface of the acromion is denuded with a radiofrequency electrocautery. Removing the soft tissue will expose the bony undersurface of the acromion and facilitate acromioplasty by the burr’s cutting flutes. C. The acromial spur is now completely visualized. The coracoacromial (CA) ligament must be completely resected from the anterolateral acromion. Failure to do so may result in residual impingement by the CA ligament. Visualization of the undersurface fibers of the deltoid indicates a complete CA ligament resection. (continued)
Part 1  SPORTS MEDICINE  •  Section I  SHOULDER

TECH FIG 2  •  (continued)  

D. The acromioplasty begins at the far anterolateral tip of the acromion. The burr's diameter, usually 5 to 6 mm, is used to assess the initial depth of the acromial resection. The acromioplasty proceeds in 5- to 6-mm strips from anterior to posterior and lateral to medial. E. Completed acromioplasty. The undersurface of the acromion is converted to a type I morphology. Any residual ridges or rough edges can be safely smoothed with the burr in the reverse cutting position. F. View of the acromioplasty from the lateral portal. At the procedure's completion, the arthroscope should be placed in the lateral portal to assess the acromion for any residual downslope or unresected bone. The acromioclavicular joint is also well visualized from this portal and may be resected or coplaned via the anterior portal. G. Coplaning of the acromioclavicular joint. The posterior or lateral portal is used for arthroscopic visualization. Coplaning is performed with the burr in the anterior or lateral portal.

- Anterior acromioplasty is performed with a 5.5-mm burr via the lateral portal.
- Resection begins in the anterolateral corner of the acromion. The desired depth of resection, estimated from the preoperative films, is obtained by measuring with the diameter of the burr (TECH FIG 2D).
- This depth of resection is achieved anteriorly from the anterolateral corner of the acromion to the medial acromial facet of the AC joint.
- The depth of resection is then progressively thinned posteriorly to the midportion of the acromion such that there is a smooth zone of transition from the anterior to the midportion of the acromion (TECH FIG 2E).
- Any ridges or rough edges may be smoothed with the burr in the “reverse cutting” position. The reverse position provides a much less aggressive bone resection, which is ideal for smoothing the bone once the acromioplasty is completed.
- The arthroscope is placed in the lateral portal to check the adequacy of resection (TECH FIG 2F). Any residual unresected acromion or impinging osteophytes from the undersurface of the AC joint should be resected.
- Radiofrequency electrocautery should be used to resect the highly vascular soft tissue on the undersurface of the AC joint.
- From the anterior or lateral portal, the 5.5-mm burr is used to coplane the distal portion of the clavicle flush with the acromion (TECH FIG 2G).

CUTTING BLOCK Technique

- Anterior acromioplasty may be carried out using the cutting block technique.
- The arthroscope is placed in the lateral portal and a 5.5-mm burr is placed in the posterior portal.
- The tip of the burr is placed on the undersurface of the anterior acromion. If type I acromial morphology is present, the burr will lie flush with the undersurface of the posterior acromion.
- The undersurface of the posterior acromion is used as a guide for resection of the anterior acromion.
- The anterior acromion is resected until the burr is flush with the undersurface of the posterior acromion, producing type I acromial morphology (TECH FIG 3).

TECH FIG 3 • Completed acromioplasty via the “cutting block” technique. The acromion is viewed from the lateral portal while the burr is used to approach the acromion from the posterior portal. The burr sits flush with the undersurface of the acromion, indicating a type I acromial morphology.
POSTOPERATIVE CARE

- Patients are placed in a sling for comfort postoperatively but are encouraged to discontinue the sling immediately when the interscalene block wears off.
- Patients are initially started on passive range-of-motion exercises. Therapy is advanced to active range of motion with terminal stretching as comfort allows. A rotator cuff and periscapular strengthening program is initiated once full range of motion is achieved. Terminal stretching, especially the posterior capsule, is continued for the next several months postoperatively.
- The therapy regimen is advanced as rapidly as motion and pain allow.
- Wounds are closed subcutaneously with 3.0 Monocryl suture.
- Steri-Strips and a sterile dressing are applied.

OUTCOMES

- The success rate for arthroscopic subacromial decompression ranges from 73% to 95%. 1-8,12,14,15
- The clinical results and predictability of bony resection for arthroscopic subacromial decompression have been shown to be equivalent to those of the open decompression. 13
- The advantages of the arthroscopic procedure far surpass those of the open procedure and include less surgical morbidity, preservation of the deltoid attachment, allowing rapid advancement of rehabilitation, and direct visualization of the glenohumeral joint. It is the senior author’s opinion that open decompression surgery for routine impingement is a dated technique that should be relegated to the status of historical interest.
- Hawkins et al.\textsuperscript{10} found a significant increase in satisfactory outcomes after arthroscopic subacromial decompression by extending the lateral portal 1.5 to 2 cm and assessing the adequacy of decompression by digital palpation.
- This technique is especially effective for surgeons early in their arthroscopic experience, where confirmation by digital palpation can give tactile as well as visual feedback on the adequacy of acromial resection.
- Coplaning impinging osteophytes from the AC joint after subacromial decompression has shown uniformly good results.\textsuperscript{3,6}
- Beveling the inferior 25% to 50% of the distal clavicle and medial acromion has resulted in neither significant AC joint hypermobility nor compromise in the outcome of subacromial decompression.\textsuperscript{3,6}
- With appropriate patient selection, combined arthroscopic subacromial decompression and distal clavicle resection for coexisting impingement syndrome and AC joint symptoms has shown excellent results with long-term follow-up.\textsuperscript{12,15}

**COMPLICATIONS**

- Infection
- Bleeding
- Neurovascular injury
- Fistula formation from excessive drainage
- Acromial fracture\textsuperscript{17}

**REFERENCES**

DEFINITION
- A number of pathologic processes may affect the acromioclavicular (AC) joint, altering anatomy, biomechanics, and normal function.
- The most common of these are primary osteoarthritis, posttraumatic arthritis, and distal clavicle osteolysis.

ANATOMY
- The AC articulation is a diarthrodial joint composed of the medial end of the acromion and the distal end of the clavicle. The joint supports the shoulder girdle through the clavicular strut.
- A fibrocartilaginous intra-articular disc is present in variable shape and size.
- The average size of the AC joint is 9 × 19 mm. The sagittal orientation of the joint surface varies, ranging from an almost vertical orientation to a downsloping medial angulation of 50 degrees.11
- The stability of the AC joint is provided by capsular (AC) ligaments, the extracapsular (coracoclavicular) ligaments, and the fascial attachments of the overlying deltoid and trapezius.
- The AC ligaments are the primary restraint to anteroposterior translation.
- The superior AC ligament, reinforced by attachments of the deltoid and trapezius fascia, resists vertical translation at small physiologic loads. However, the coracoclavicular ligaments are the primary restraint to superior displacement under large loads.

PATHOGENESIS
- Degeneration of the AC joint is a natural part of aging.
  - DePalma11 has shown degeneration of the fibrocartilaginous disc as early as the second decade of life and degenerative changes in the AC joint commonly by the fourth decade.
  - The superficial location of the joint may predispose it to traumatic injury.
  - The clavicle acts as a supporting strut for the scapula, helping maintain its orientation and biomechanical advantage for glenohumeral motion. Large forces may be transmitted from the extremity to the axial skeleton through the small surface area (9 × 19 mm) of the AC joint.
- Repetitive transmission of large forces, such as weightlifting or heavy labor, may result in degeneration of the joint.
- Repetitive microtrauma to the AC joint may cause subchondral fatigue fractures that undergo a subsequent hypervascular response, resulting in reabsorption and osteolysis (distal clavicular osteolysis).

NATURAL HISTORY
- Despite the frequency of radiographically evident AC joint degeneration, symptomatic arthritis of the AC joint is relatively uncommon.
- Studies have shown that 8% to 42% of patients with type I and II AC joint injuries develop chronic AC symptoms from posttraumatic arthritis.2,3
- Distal clavicle fractures may also result in posttraumatic arthritis.
- Patients with symptomatic AC joint degeneration have been successfully treated nonoperatively with activity modification.12

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with isolated AC pathology typically experience pain over the anterior or superior aspect of the shoulder in an area between the midpart of the clavicle and the deltoid insertion.
- Pain occurs with activities of daily living that involve internal rotation and adduction such as putting on a coat sleeve, hooking a brassiere, or washing the opposite axilla.
- Younger patients may complain of pain with weightlifting, golf swing follow-through, swimming, or throwing.
- Physical examination of the AC joint includes:
  - Palpation: Tenderness on direct palpation suggests AC pathology.
  - Cross-arm adduction test: This test is highly sensitive but not specific for AC pathology; it is often positive with impingement syndrome. Pain should be confirmed anteriorly because this maneuver will cause posterior pain if posterior capsular tightness is present.
  - Paxinos test: Combined with a bone scan, this test was found to be the most predictive factor for AC joint pathology.16
  - Diagnostic AC injection: Elimination of symptoms is diagnostic of AC pathology and prognostic for successful distal clavicle resection.
  - A complete physical examination of the shoulder should be done to evaluate associated pathology and to rule out other differential diagnoses (as described below).
- Impingement syndrome commonly coexists with or may mimic AC pathology, and awareness of this possibility should be used to rule out its existence.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The AC joint is best evaluated radiologically with a Zanca view. This provides an unobstructed view of the AC joint by tilting the x-ray beam 10 to 15 degrees cephalad of the normal shoulder AP (FIG 1A).
- Characteristic radiographic changes of primary and posttraumatic arthritis of the AC joint include osteophyte formation with trumpeting of the distal clavicle, sclerosis, and subchondral cyst formation. Narrowing of the AC joint will also be present; however, this occurs as a normal part of aging.
Rheumatoid arthritis affecting the AC joint would typically show periarticular erosions and osteopenia with less spurring than osteoarthritis.

Distal clavicle osteolysis characteristically shows osteopenia, cystic changes of the distal clavicle, and widening of the joint space with narrowing of the distal clavicle.

The supraspinatus outlet view may show inferior clavicular osteophytes, which may contribute to an impingement syndrome.

The axillary lateral view of the shoulder may show anterior or posterior displacement of the clavicle, indicative of trauma to the AC joint.

Three-phase technetium bone scan is highly sensitive and specific for AC joint pathology that is not evident with conventional radiography.

Magnetic resonance imaging (MRI) is sensitive in identifying AC pathology but has poor specificity, as AC abnormalities are frequently observed in clinically asymptomatic patients. Reactive edema in the AC joint is more predictive of clinical symptoms than are MRI findings of degenerative changes in the AC joint (FIG 1B).

Differential Diagnosis

- Intrinsic shoulder pathology
- Impingement syndrome
- Rotator cuff tears
- Biceps lesions
- Glenohumeral arthritis
- Early adhesive capsulitis
- Musculoskeletal tumors of the distal clavicle and proximal acromion
- Extrinsic conditions
  - Cervical spine disorder
  - Referred visceral problems (cardiac, pulmonary, or gastrointestinal disorders)

Nonoperative Management

- The initial management of painful AC pathology should be conservative and should include a combination of activity modification, ice or heat therapy, nonsteroidal anti-inflammatory medications, corticosteroid injection, and physical therapy.
- Activity modification should focus on avoiding the inciting painful activities. Some patients may be successfully treated nonoperatively with activity modification.
- Intra-articular corticosteroid injection with 1 mL of 1% lidocaine and 1 mL of corticosteroid is effective in relieving AC joint pain, but the duration of relief is variable. Patients may receive multiple injections.
- Physical therapy consisting of terminal stretching and rotator cuff strengthening may be effective if a concomitant impingement syndrome exists. Isolated AC pathology typically does not respond to physical therapy.
- Patients should undergo 3 to 6 months of conservative management before operative intervention.

Surgical Management

- Patients with continued AC joint symptoms despite adequate conservative management over a 3- to 6-month period are appropriate candidates for surgical intervention.
- Significant pain relief from an AC joint injection should be documented before surgery, as this is prognostic for a good result after distal clavicle excision.

Preoperative Planning

- Preoperative history, physical examination, and imaging studies should be reviewed before operative intervention.
- A lidocaine injection test should be completed preoperatively and the patient should experience significant pain relief.
- If the diagnosis is in doubt and the patient does not receive significant pain relief from the lidocaine injection, a more detailed workup should be completed before surgery.
- Error in diagnosis accounts for a significant number of failures of distal clavicle resections.

Positioning

- The patient may be placed in the beach-chair or lateral decubitus position.
- We prefer the beach-chair position, as it facilitates conversion to an open procedure such as biceps tenodesis. The beach-chair position also places the AC joint in its more customary in vivo orientation, which may aid the surgeon during arthroscopy.

Approach

- There are two methods to resect the distal clavicle: the indirect (subacromial) approach and the direct (superior) approach.
The choice of approach depends on the presence of concomitant shoulder pathology and the status of the AC joint. The indirect approach is used when there is coexisting shoulder pathology, such as an impingement syndrome or a rotator cuff tear, allowing the patient to undergo simultaneous subacromial decompression and rotator cuff repair. The indirect approach is also helpful for markedly narrow AC joints, allowing wider exposure and thus better visualization of the AC joint surfaces.

The direct approach may be used for patients with isolated AC pathology or if there is adequate joint space to place the burr. We prefer the indirect (subacromial) approach to resect the distal clavicle because associated pathology can be addressed, fewer incisions are made, and the joint can be easily and adequately resected from this approach.

### INDIRECT (SUBACROMIAL) DISTAL CLAVICLE RESECTION

- A complete diagnostic arthroscopy of the glenohumeral joint is performed.
- The arthroscope is redirected into the subacromial space through the posterior portal.
- A complete bursectomy and diagnostic subacromial arthroscopy is performed, as described in the previous section on subacromial decompression.
- If an impinging spur from the acromion or an osteophyte from the inferior AC joint is present, subacromial decompression and coplaning of the AC joint are performed, as previously described.
- The AC joint may be difficult to orient due to variations in patient anatomy. An 18-gauge spinal needle may be placed percutaneously into the AC joint to facilitate orientation (TECH FIG 1A).
- If coplaning of the AC joint has not been previously performed with the subacromial decompression, an electrocautery device is used to remove the soft tissue from the undersurface of the AC joint.
- A 5- to 6-mm burr is then inserted in the lateral portal and the acromial side of the AC joint is resected. This will expose the distal aspect of the clavicle (TECH FIG 1B).
- Both the acromial and clavicular sides of the AC joint should be beveled. This maneuver will create more working space and will allow easier access to the AC joint once the burr is introduced into the anterior

**TECH FIG 1** • A. A spinal needle may be placed in the AC joint to help orient the surgeon. B. View of the AC joint from the posterior portal. The burr is in the lateral portal and is used to take down the acromial side of the AC joint. This maneuver will decompress the subacromial space and help expose the distal clavicle. C. Beveling the distal clavicle. With the burr in the lateral portal, the undersurface of the distal clavicle is scored. The surgeon can base the amount of clavicular resection on the length of the burr. D. The arthroscope is placed in the lateral portal and the burr is introduced into the AC joint via the anterior portal. The resection is completed using the landmarks established when previously beveling the distal clavicle. E. The completed AC joint resection is viewed “end on” from the lateral portal. F. The arthroscope is introduced into the anterior portal to view the adequacy of the posterior AC resection. The resection is adequate. The posterior AC joint capsule is left intact.
portal. Inferiorly directed pressure over the distal clavicle will also enhance its visualization.

- The burr tip is about 10 to 12 mm long. Thus, when approaching the distal clavicle from the lateral portal, the length of the burr tip can be used to measure the length of distal clavicle to be resected, typically 8 to 10 mm (TECH FIG 1C).
- Care should be taken to preserve the anterior and posterior AC ligaments if possible. The inferior joint capsule will be resected with the indirect approach.
- The arthroscope is now placed in the lateral portal and the 5.5-mm burr is placed in the anterior portal (TECH FIG 1D).
- The burr is placed in the beveled area previously established via the lateral portal.
- Resection of the remaining dorsal two thirds of the distal clavicle is accomplished starting at the anteroinferior aspect of the distal clavicle and working in a posteroinferior direction.
- Again, care is taken to preserve the superior and posterior AC ligaments and superior joint capsule.
- About 1 cm of the distal clavicle is resected. Again, this can be estimated by comparing the size of the resection with the size of the burr (TECH FIG 1E).
- The arthroscope is then placed in the anterior portal to evaluate the adequacy of resection (TECH FIG 1F).
- The arm may be placed in maximal cross-body adduction with the arthroscope in the anterior portal to confirm that the ends of the acromion and clavicle do not touch.

**DIRECT (SUPERIOR) DISTAL CLAVICLE RESECTION**

- A portal for the arthroscope is placed superiorly, 1 cm posterior to the AC joint. A 5-mm incision is made to introduce the trocar for the arthroscope.
- Once the arthroscope is introduced, the anterior working portal is placed under direct visualization starting superior and 1 cm anterior to the AC joint (TECH FIG 2A).
- A smaller arthroscope (2.7 mm) and soft tissue resector (2.0 mm) may be needed initially if the AC joint is significantly narrowed (TECH FIG 2B).
- An electrocautery device is used to remove the soft tissue on the AC joint undersurface.
- The AC joint is progressively resected until a larger burr (5.5 mm) will fit into the joint space.

**WOUND CLOSURE**

- As much fluid as possible is drained from the subacromial and intra-articular space. Suction may be placed on the arthroscopic cannula's outflow port to speed the extraction of superfluous fluid.
- Wounds are closed subcutaneously with 3.0 Monocryl suture.
- Steri-Strips and a sterile dressing are applied.
**PEARLS AND PITFALLS**

| Diagnostic error | - Diagnostic error is a common cause of failure of distal clavicle resection. A careful history and physical examination must be done before operative intervention. Patients must have significant relief of acromioclavicular (AC) symptoms after the intra-articular lidocaine injection test. A positive injection test is also prognostic for a good outcome after distal clavicle resection.  
- Many patients may have radiographic evidence of AC degeneration, but often these patients have no clinical symptoms. Symptomatic patients frequently have osseous edema on MRI evaluation of the AC joint. |
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>AC joint orientation</td>
<td>- It may be difficult to discern the orientation of the AC joint from subacromial space. Eighteen-cm of distal clavicle resection is adequate for successful operative treatment; care should be taken to preserve as much of the AC capsular ligaments as possible, especially during orientation. Visualization of the distal clavicle may be enhanced by resecting the medial aspect of the acromion and using inferior-directed pressure over the distal end of the clavicle.</td>
</tr>
</tbody>
</table>
| Inadequate distal clavicle resection | - This is a common technical error resulting in surgical failure.  
- Inadequate resection of the posterior and superior cortical ridge commonly causes residual abutment against the acromion.  
- One centimeter of distal clavicle resection is adequate for successful operative treatment; however, the adequacy of resection should be assessed in each case by dynamic cross-arm adduction with the arthroscope in the anterior portal.  
- If there is any question regarding the adequacy of resection, the anterior portal may be extended 1 cm superiorly and the resection may be assessed by direct digital palpation. |
| AC joint instability | - Care should be taken to preserve as much of the AC capsular ligaments as possible, especially during the superior ligament, which provides the primary resistance to posteriorly directed forces. Inadvertent release of the coracoclavicular ligaments should also be avoided because they resist axial compression of the AC joint. Thus, loss of coracoclavicular ligament function may cause abutment between the distal clavicle and acromion despite adequate bony resection. |

**POSTOPERATIVE CARE**

- Patients are placed in a sling for comfort postoperatively but are encouraged to discontinue the sling immediately when the interscalene block wears off.  
- Patients are started on passive range-of-motion exercises for the first postoperative week. Therapy is advanced to active range of motion with terminal stretching in the second postoperative week. A resisted rotator cuff and periscapular strengthening program is initiated the third week postoperatively. Terminal stretching is continued for the next several months postoperatively, especially posterior capsule stretches.  
- The therapy regimen is advanced as rapidly as motion and pain allow.  
- Patients can typically return to sport in 2 to 3 months. Graduated return is advised. For example, golfers should only chip and putt for the first month postoperatively. Weightlifters can begin training with lighter weights and avoid pressing motions until comfortable.  
- The quicker recovery time is a result of deltoid attachment preservation, which eliminates postoperative protection of the deltoid and allows for rapid advancement of physical therapy.  

**OUTCOMES**

- The published success rates of arthroscopic distal clavicle resection are generally good and parallel the results of open distal clavicle resection.  
- Good or excellent outcomes have been reported in 83% to 100% of patients undergoing arthroscopic distal clavicle resection for primary osteoarthritis, posttraumatic osteoarthritis, or distal clavicle osteolysis. 
- The results of open versus arthroscopic distal clavicle resection have been retrospectively reviewed in the literature.  
- Several authors have found equivalent long-term results of open and arthroscopic distal clavicle resections; however, a significantly quicker recovery time has been observed with the arthroscopic resection.  
- The quicker recovery time is a result of deltoid attachment preservation, which eliminates postoperative protection of the deltoid and allows for rapid advancement of physical therapy.  

**COMPLICATIONS**

- Infection  
- Bleeding  
- Neurovascular injury  
- AC joint instability  
- Painful scar formation  
- Heterotopic ossification at the resection site

**REFERENCES**

DEFINITION

- Rotator cuff disease encompasses a spectrum of disorders ranging from tendinitis to partial and full-thickness tendon tearing.
- It is the most common shoulder disorder treated by an orthopedic surgeon, with over 17 million U.S. individuals at risk for the disabilities caused by the disease.
- The prevalence of full-thickness tearing of the rotator cuff ranges from 7% to 40% across multiple studies.  
- Age-related degenerative change is a primary factor in the development of rotator cuff tears.  
  - Asymptomatic full-thickness tears have been found in 13% of the population between age 50 and 59 and in over 50% of people older than 80 years old.  
  - The risks and benefits of both nonoperative and operative treatment must be considered for each individual patient.
- A number of factors are critical in deciding how to treat full-thickness tears, including a history of trauma, patient age, tear size, degenerative muscle and tendon changes, and functional disability.
- Traditionally, open rotator cuff repair was the standard of care for symptomatic full-thickness rotator cuff tears.
  - Several disadvantages are inherent to open rotator cuff repairs. These include the need for deltoid detachment, difficult visualization of associated glenohumeral joint pathology, larger incisions, more extensive surgical dissection, and potentially a higher infection rate.
- The surgical treatment of full-thickness rotator cuff tears has been revolutionized by the advent of arthroscopic surgery.
  - With the introduction of arthroscopy, rotator cuff repair has moved from mini-open repairs to complete arthroscopic repairs.
  - As techniques of complete arthroscopic rotator cuff repair have advanced, attempts have been made to treat larger tears arthroscopically. To do this, stronger fixation constructs must be used.
  - Single-row suture anchor repairs have been reported with good overall clinical results, but healing rates decrease as tear size increases.  
  - Double-row repair constructs with a medial and lateral row have been shown to provide improved initial biomechanical strength and restoration of the normal anatomic rotator cuff footprint.  
  - In the setting of a full-thickness rotator cuff tear, we now perform a double-row suture anchor repair if technically possible. While the double-row repair is more technically demanding, the potential advantages of anatomic restoration of the tendon insertion, improved biomechanical fixation, and improved healing may lead to improved functional outcomes.

ANATOMY

- The rotator cuff is a complex of four muscles arising from the scapula and inserting onto the tuberosities of the proximal humerus.
  - The supraspinatus and infraspinatus muscles make up two thirds of the posterior cuff. The two tendons fuse together and have a direct bony insertion.
  - When performing a double-row rotator cuff repair, knowledge of the dimensions of the rotator cuff insertion or “footprint” is critical.
  - The supraspinatus averages 25 mm wide and has a medial-to-lateral footprint (tendon attachment) of 12.1 mm at the midtendon (Figure 1).
  - There is a normal sulcus between the articular cartilage and the medial aspect of the supraspinatus footprint; it averages 1.5 mm in width.
  - The infraspinatus has been shown to average 29 mm wide, with a mean medial-to-lateral width of 19 mm.
  - Suture anchor repair constructs using a single row of anchors have been shown to restore only 67% of the original footprint of the rotator cuff.
  - Adding a second row of anchors increases the contact area of the repair 60%.
  - The biomechanical properties of the double-row repair are improved compared to single-row repairs and include decreased strain over the footprint area, increased stiffness, and increased ultimate failure load.

PATHOGENESIS

- The etiology of rotator cuff tears is multifactorial.
  - The major factors are age-related degenerative changes of the tendon and physiologic loading.
  - The theory of age-related accumulative damage is supported by histologic findings of decreased fibrocartilage at the cuff insertion, decreased vascularity, fragmentation of the tendon with cellular loss, and disruption of Sharpey fiber attachments to bone.
  - Clinical studies support the aging theory as a primary cause of rotator cuff disorders.  
    - In a recent review of 586 consecutive patients with unilateral shoulder pain, rotator cuff tears were found to be correlated with increasing age, with an almost perfect 10-year difference between patients with no tear, a unilateral tear, and bilateral tears.
    - The average age of patients presenting with rotator cuff-derived pain with no tear was 48.7 years old; unilateral tear, 58.7 years old; and bilateral tears, 67.8 years old.
  - Physiologic loading of the tendon has also been postulated as a mechanism for cuff tearing.
  - Localized degeneration of the articular region of the tendon, most commonly in the supraspinatus, is indicative of a tendon loading etiology.
NATURAL HISTORY

- Uniform changes throughout the entire tendon, which are not commonly found, would be more suggestive of an age-related degenerative process.
- Age and loading likely have a multiplicative effect, with tendons in an older person both being more susceptible to damage from normal physiologic loading and exhibiting a worse healing response.
- Genetics may also have a significant role in the predisposition for rotator cuff tears.
  - A strong relationship between rotator cuff tearing and family history has been shown.
  - One study found a relative risk of 2.42 for full-thickness rotator cuff tears in siblings of patients with cuff tears versus controls.10
  - This increased risk in siblings implies that genetic factors may play a role in the development of rotator cuff tears.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with rotator cuff disorders often complain of pain, weakness, or both in the shoulder.
- The development of symptoms is often insidious.
  - There may be a recollection of minor trauma (eg, episode of heavy lifting, catching a heavy object).
  - Pain is usually localized to the anterior or anterolateral aspect of the shoulder, often extending down the front or side of the shoulder to the elbow.
  - Pain exacerbated with use, especially with overhead activities, is common.
  - Sleep disruption is also common in patients with symptomatic rotator cuff disease.
- Weakness is a complaint for patients with large full-thickness rotator cuff tears.
  - Pain from tendinitis or small tears may simulate lack of strength, however. Therefore, weakness alone is not diagnostic of a large tear.
  - Similarly, patients with large or massive tears may have very reasonable function.
  - More commonly, however, these patients report overhead weakness and fatigue.
  - If gross weakness is recognized suddenly after a trauma, a rotator cuff injury should be suspected and investigated.
- In the setting of chronic rotator cuff tears, inspection of the shoulder will often reveal atrophy of the supraspinatus and infraspinatus.
  - Prior surgical incisions should be noted. If previous open rotator cuff repair with deltoid detachment was performed, deltoid repair integrity should be assessed, along with axillary nerve function.
  - Range-of-motion testing should be performed both actively and passively.
  - Passive range of motion is often preserved except in the setting of chronic large tears, where static superior head migration leads to limited forward elevation with inferior capsule contracture.
  - Posterior capsular contracture is also a common finding with both small and large tears.
Active motion is often limited in scapular plane elevation. This may be due to either weakness or pain.

Shoulder strength should be evaluated with manual muscle testing.

Various arm positions will isolate the rotator cuff and specifically test these muscles for dysfunction.

The supraspinatus, infraspinatus, and teres minor can be isolated with resisted scapular plane elevation at 90 degrees in neutral rotation, resisted external rotation in full adduction and slight internal rotation, and external rotation in 90 degrees of abduction and 90 degrees of adduction, respectively.

Either the belly-press or lift-off test can be used to test subscapularis function.

Belly-press test: Inability to maintain maximum internal rotation without the elbow dropping posterior to the midsagittal plane of the trunk indicates impaired subscapularis function.

Lift-off test: Inability to maintain active maximal internal rotation with hand off the lumbar spine without extending the elbow indicates impaired subscapularis function.

Electromyographic analysis has shown that the belly-press activates the upper subscapularis while the lift-off activates the lower subscapularis.

Painful limitation of motion may limit the usefulness of the lift-off test.

This information may improve our ability to determine the extent of subscapularis dysfunction.

Special tests have been developed to aid in diagnosis:

The Neer impingement test (forward elevation in internal rotation) and the Hawkins impingement test (elevation to 90 degrees, cross-body adduction and internal rotation) were designed to elicit symptoms by impinging the rotator cuff on the undersurface of the acromion and coracoacromial ligament.

The Hornblower sign indicates teres minor dysfunction or tearing if there is weakness or inability to achieve full external rotation in an abducted position.

A positive result (weakness or pain) in the empty can test (Jobes sign) indicates dysfunction of the supraspinatus tendon.

Weakness with resisted external rotation in adduction represents dysfunction or tearing of the infraspinatus tendon.

External rotation lag sign: Inability to maintain the shoulder in a fully externally rotated position indicates significant dysfunction or tearing of the infraspinatus muscle.

Variable accuracy of these tests has been shown when used in isolation, but accuracy may be improved when used in combination with other provocative examinations.

We do not routinely use these examinations, however. Instead, we base our findings on pain or weakness with resisted strength testing.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Four standard shoulder radiographs should be taken of every patient evaluated for shoulder pain: anteroposterior (AP), true AP with active shoulder abduction, axillary lateral, and scapular-Y views.

The decision to obtain further imaging studies is based on radiographic findings along with data obtained from the history and physical examination.

In a patient with a small full-thickness rotator cuff tear, radiographs are usually normal.

With increasing tear chronicity, sclerotic and cystic changes of the greater tuberosity are often noted.

With increasing tear size, proximal humeral migration can be found on the AP and true AP views.

Proximal migration is best identified on the true AP view as loss of a concentric reduction of the proximal humeral and glenoid centers of rotation.

Humeral elevation may be static or dynamic depending on the chronicity of the tear. Static elevation occurs with contracture of the inferior capsule.

Narrowing of the acromiohumeral interval on the AP view has also been used to identify large tears.

MRI of the shoulder in patients with rotator cuff tears evaluates both the tendon and muscle quality.

Full-thickness tears show increased signal intensity at the tendon insertion on T2-weighted images.

MRI has been shown to have over 90% sensitivity and specificity in detecting tears without previous surgery.

Fatty infiltration and atrophy of the rotator cuff musculature can also be identified on MRI.

Increased fatty infiltration of the rotator cuff muscles has been correlated with poorer tendon healing and worse final postoperative outcomes after repair.

In the hands of a skilled ultrasonographer, ultrasound has a sensitivity and specificity similar to that of MRI.

Benefits of ultrasound include limited radiation, ability to routinely perform bilateral examinations, and a dynamic component of the examination, which can significantly aid in differentiating scar from tendon.

The most significant limitation of ultrasound is the need for an experienced ultrasonographer.

CT and CT arthrography has been widely used in Europe for the diagnosis of rotator cuff tears.

In patients with pacemakers or aneurysm clips, CT arthrography is a good alternative to MRI. Limitations of CT include increased radiation exposure and poorer soft tissue resolution compared to MRI.

Similar to MRI, muscle quality, including atrophy and fatty infiltration, can be examined and has been shown to be predictive of tendon healing and outcomes after surgery.

**DIFFERENTIAL DIAGNOSIS**

- Rotator cuff tendinitis
- Partial-thickness rotator cuff tear
- Rotator cuff contusion
- Adhesive capsulitis
- Arthritis or chondral injury
- Calcific tendinitis
- Biceps tendon pathology (tendinitis or tearing)
- Suprascapular nerve entrapment or spinoglenoid notch cyst
- Internal impingement

**NONOPERATIVE MANAGEMENT**

The decision to pursue nonoperative management in the setting of a full-thickness rotator cuff tear depends on both patient and tear characteristics. Asymptomatic tears are extremely common, with MRI, ultrasound, and arthrography studies showing a 4% to 13% incidence in subjects 40 to 60 years old and over 50% in subjects older than 80. All asymptomatic
Tears should be treated nonoperatively. In subjects younger than 65, serial monitoring with sequential MRI or ultrasounds is reasonable, given that over 51% of patients with a previously asymptomatic tear and a contralateral symptomatic tear will develop symptoms in the asymptomatic shoulder over an average of 2.8 years.25

For symptomatic tears, nonoperative treatment has shown moderate success, with 45% to 82% satisfactory results.4,11,22 Nonoperative treatment includes anti-inflammatory medications, shoulder stretching, and rotator cuff and scapular stabilizer strengthening exercises. A limited number of subacromial cortisone injections may be performed, especially in patients who are not surgical candidates. Chronic large or massive rotator cuff tears in any age group or any chronic full-thickness tear in patients older than age 70 should undergo an initial trial (at least 3 months) of nonoperative management. Because irreversible changes have already occurred to the cuff or the articular cartilage in most of these patients, it is safe to attempt nonoperative treatment for a period of time. Failure of nonsurgical treatment is an indication for arthroscopic repair.

SURGICAL MANAGEMENT

The decision to proceed with operative treatment of rotator cuff disease requires an evaluation of the risks and benefits associated with both surgical and nonsurgical treatment.

While the risks of surgical management are well known, the risks of nonoperative treatment may not be so obvious.

- Tear progression, muscle fatty infiltration and atrophy, and arthritis are potential irreversible risks of nonoperative treatment of rotator cuff tears.
- Knowledge about these risks can help guide treatment.

Early surgical repair should be considered in all acute tears and any chronic small or medium-sized tears in patients younger than age 65.

These patients are at significant risk for developing the irreversible changes previously mentioned with prolonged nonoperative treatment.

These patients also have the greatest potential for healing. Consequently, the benefits of early surgical treatment combined with the inherent risks of prolonged nonoperative treatment guide us to early surgical repair.

Preoperative Planning

Tear size and chronicity will determine the difficulty of the repair, so careful preoperative imaging evaluation is important in surgical preparation.

- If a tear is very large, the surgeon should make sure that a variety of different suture-passing devices are available to assist in the repair.
- A Banana Suture Lasso (Arthrex, Naples, FL) can be passed through the Neviser portal in large, medially retracted tears to shuttle suture through the tendon.
- Angled Suture Lassos (Arthrex) can be placed through accessory portals to pass sutures from difficult angles not easily approached through the lateral working cannulas.
- Larger anchors should be available if bone quality is poor.
- Assess preoperative motion after the patient is anesthetized but before initiating the surgical procedure. Fixed superior humeral migration in the setting of a large rotator cuff tear will lead to inferior capsular contracture. In these patients, perform preoperative manipulation under anesthesia in forward elevation to increase the subacromial space available, thus facilitating the repair.

Positioning

- Beach-chair position advantages
  - This is an anatomic position that permits better orientation and understanding of shoulder anatomy while performing the repair.
  - Examination under anesthesia is facilitated by stabilizing the scapula in the beach-chair position compared with the lateral position.
  - The arm can be easily manipulated in surgery without the need to unhook it from a traction unit.
  - Traction is not required but can be added in an inferior direction to increase the subacromial working space.
  - Humeral rotational control is easily accomplished. This can be critical when working on different regions (anterior vs. posterior) of the greater tuberosity.
  - Conversion to an open procedure is easily performed without redraping.
- Lateral decubitus position advantages
  - Many surgeons believe that the lateral position improves visualization and maneuverability of the scope due to traction.
  - It significantly improves inferior access to the glenohumeral joint, which makes it less difficult to perform glenohumeral procedures but has little impact on subacromial procedures.
  - Transient and permanent nerve damage has been reported due to traction in the lateral position. Consequently, we prefer to perform all subacromial procedures, including rotator cuff repair, in the beach-chair position.

DOUBLE-ROW ROTATOR CUFF REPAIR WITH “MASON-ALLEN”-TYPE CONSTRUCT USING SCREW-IN SUTURE ANCHORS

Portal Placement and Cannula Insertion

- The camera is placed in the subacromial space through a posterior portal.
- Our preferred starting posterior portal is slightly more lateral than a standard posterior portal. This is done to gain better visualization of the lateral greater tuberosity during repair. Also, a slightly inferior position is preferred, since portals will migrate superiorly with shoulder swelling.
- A lateral working portal is developed under spinal needle localization. Portals should be placed low enough so that cannulas are introduced parallel to the rotator cuff tendon. This allows for easier subacromial instrumentation. The portal should be placed at about the midpoint of the tear in small or medium-sized tears.
- A second lateral portal can be placed in larger tears with cannulas separated by several centimeters. Clear fully threaded 8.25-mm cannulas are placed in these portal sites.
Another large threaded cannula is placed through an anterolateral portal, anterior to the acromion, at the same level as the lateral and posterior portals. Again, maintaining low portal placement is critical so instruments will be passed parallel to the tendon, allowing the greatest excursion of instruments in the subacromial space. The anterolateral portal is mainly used as an accessory portal for suture retrieval and storage.

**Repair Site Preparation**
- A soft tissue ablation device is used through the lateral portal to clear all the soft tissue on the undersurface of the acromion extending posteriorly, including the soft tissue and fat around the scapular spine. This will significantly improve the mobility of the tear. Soft tissue is removed from the greater tuberosity with a shaver, exposing cortical bone.
- Mobility of the torn tendon is assessed with a tissue grasper through the lateral portal.

**Anchor and Suture Placement**
- Once the tear has been determined to be repairable, a medial row of suture anchors (5.5-mm metal screw-in style) is placed. Anchors are loaded with two no. 2 Fiberwire sutures (Arthrex).
- For small and medium-sized tears, we routinely place two medial anchors at the level of the anatomic neck. Each anchor is separated by 1 to 1.5 cm. Anchors are placed through small stab incisions just off the lateral border of the acromion.
- For large and massive tears, we place three medial anchors.
- Sutures from the medial row of anchors are next passed through the tendon. Starting with the most anterior anchor, both strands from one suture are passed through the tendon at the anterior aspect of the tear in a horizontal mattress fashion. Sutures are passed approximately 1 cm medial to the lateral edge of the tear. One strand of the second suture is passed adjacent to the most posterior strand of the first suture. This strand is retrieved out the anterolateral portal along with the two strands of the first suture.
- The steps are repeated for the posterior anchor of the medial row. Two strands of one suture are passed at the posterior aspect of the tear in a mattress fashion. One strand of the second suture is placed just anterior to the previously placed mattress suture and retrieved out the anterolateral portal.
- Both strands of the posterior mattress stitch are retrieved out the lateral portal, tied arthroscopically, and cut. Similarly, both strands of the anterior mattress stitch are retrieved out the lateral portal, tied, and cut.
- The remaining strands passed through the tendon are in the anterolateral cannula and tied to one another outside the shoulder. The tails are cut and the knot is then advanced into the shoulder by pulling on the opposite two strands of the two sutures, creating a large horizontal mattress stitch between the anterior and posterior anchors (TECH FIG 1A).
- A single lateral suture anchor is then placed at the lateral aspect of the rotator cuff footprint on the greater

---

**TECH FIG 1** - A. Arthroscopic picture showing the bridging horizontal mattress stitch between two medial-row anchors. Suture strands on right are the other limbs of the horizontal mattress stitch, which will be tied arthroscopically after the lateral-row stitches have been passed and tied. B. Lateral-row suture anchor placed at the lateral aspect of the greater tuberosity between the two medial-row anchors. C. Passage of lateral-row stitches medial to the bridging medial-row horizontal mattress stitch with a Scorpion suture passer. D. Final repair construct of a double-row repair using two medial and one lateral screw-in suture anchors.
tuberosity, halfway between the medial anchors (TECH FIG 1B). One strand of one suture is retrieved out the lateral portal and passed medial to the horizontal stitch between the anterior and posterior medial anchors.

- This step is repeated with the second suture from the lateral anchor. These stitches are passed using a Scorpion suture passer (Arthrex) (TECH FIG 1C).

- Once the lateral anchor sutures are passed, the remaining strands from the medial sutures are pulled on by an assistant to tension the medial horizontal mattress stitch between the medial anchors while the lateral-row sutures are tied. While tension is applied to the medial row, the lateral simple stitches are tied arthroscopically and cut.

- Finally, the remaining two strands from the medial row anchors are retrieved out the lateral portal and tied arthroscopically.

- The final construct has two medial-row anchors with a mattress stitch between the anchors and one lateral anchor with two simple stitches passed medial to the horizontal mattress between the medial anchors. This creates a “Mason-Allen” type of construct with the lateral simple stitches passed medial to the bridging medial horizontal mattress stitch (TECH FIG 1D).

DOUBLED-ROW ROTATOR CUFF TEAR WITH “MASON-ALLEN”-TYPE CONSTRUCT USING MEDIAL SCREW-IN SUTURE ANCHORS AND LATERAL PUSHLOCK ANCHORS

- This repair technique follows the previous repair technique. After the anterior and posterior medial-row mattress sutures are tied, the tails of these sutures are not cut. Instead, they are retrieved out the anterolateral portal and stored. The bridging horizontal mattress stitch between the two medial anchors is created as described in the previous technique.

- The untied suture strands (one from the anterior anchor and one from the posterior anchor) from the bridging mattress stitch between the anterior and posterior anchors (TECH FIG 2A) are retrieved out the lateral portal.

- Both suture strands are then passed simultaneously medial to the horizontal mattress bridging mattress stitch with the Scorpion suture passer (Arthrex). This creates a Mason-Allen type of locking stitch construct.

- Through one of the accessory lateral portals where the medial-row anchors were placed, a suture retriever is placed. Three strands are grabbed with the retriever: one strand from the tied posterior mattress stitch, one strand from the tied anterior mattress stitch, and one of the strands passed medial to the bridging horizontal mattress stitch.

- All three strands are placed in a PEEK 3.5-mm PushLock knotless suture anchor (Arthrex). The PushLock awl is placed through the same lateral accessory portal and an anchor hole is tapped along the lateral aspect of the greater tuberosity at the posterior aspect of the tear (TECH FIG 2B). After a hole is tapped, the anchor is introduced into the joint through the same portal and impacted into the hole. The PushLock anchor has three strands (one strand from the tied posterior mattress stitch, one strand from the tied anterior mattress stitch, and one of the strands passed medial to the bridging horizontal mattress stitch) (TECH FIG 2C). As the anchor is impacted, all three strands should be tensioned to reduce the rotator cuff to the footprint. All three strands are then cut after final impaction of the PushLock anchor.

- The previous steps are repeated, grabbing the second suture strand from the anterior and posterior mattress stitches and the second strand passed medial to the bridging mattress stitch. All three are placed in a second PushLock anchor and an anchor pilot hole is created at the anterior aspect of the tear along the lateral aspect of the greater tuberosity footprint.

TECH FIG 2 • A. Arthroscopic picture showing the opposite ends of the bridging horizontal mattress stitch shuttled through the cuff tendon medial to the bridging mattress stitch. B. A pilot hole is created using an awl for the posterior PushLock anchor as part of the lateral row. C. The posterior PushLock anchor is placed with one strand of suture from the anterior horizontal mattress stitch, one strand from the posterior horizontal mattress stitch, and one limb of the sutures from the bridging mattress stitch. (continued)
Chapter 10 ARTHROSCOPIC TREATMENT OF ROTATOR CUFF TEARS

After pilot hole creation, the anchor is introduced into the joint. With all three suture strands and while the strands are tensioned, the anchor is impacted (TECH FIG 2D). The tails of all three strands are then cut flush with the PushLock anchor, completing the repair.

The final construct consists of two medial-row anchors and two lateral-row PushLock anchors (TECH FIG 2E,F). Only two arthroscopic knots are required to complete this double-row repair.

PEARLS AND PITFALLS

| Portal placement | ▪ The posterior portal should be placed more lateral than the standard portal site (standard portal site: 2 cm medial and 2 cm inferior to the posterolateral corner of the acromion) for improved access to the lateral aspect of the greater tuberosity.
  | ▪ Portal placement should err low to facilitate instrumentation after shoulder swelling. |
| Surgical anatomy | ▪ Landmarks should be precisely drawn on the shoulder before arthroscopy to ensure accurate portal placement. |
| Preoperative examination under anesthesia and manipulation | ▪ With large, chronic rotator cuff tears, fixed superior humeral migration is often present. Preoperative manipulation in forward elevation will assist in releasing the inferior capsule, thereby allowing improved access to the subacromial space with inferior traction during surgery. |
| Hemostasis | ▪ Preoperative (5 to 10 minutes) subacromial injection of local anesthetic with epinephrine in the subacromial space will significantly reduce bleeding during repair. During soft tissue removal around the scapular spine and coracoacromial ligament release along the anteroinferior acromion, the surgeon must watch for vessels that require coagulation. |
| Passage of lateral low stitches medial to medial horizontal mattress | ▪ During passage of the lateral stitches, any resistance to suture passage may mean impalement of previously placed medial-row sutures. If resistance is met, the suture passer should be removed and reloaded without forcing suture passage. |
| Lateral row PushLock anchor placement | ▪ After PushLock anchors are loaded with suture outside the shoulder, they should be placed through the same fascial defect through which sutures were retrieved, thereby preventing suture entanglement in the deltoid fascia. |
POSTOPERATIVE CARE

- All patients are initially placed in a sling, which is removed only for elbow range-of-motion exercises three or four times per day to limit elbow stiffness and for bathing.
- We use a subacromial pain catheter, infiltrating 0.5% bupivacaine (Marcaine) during the first 48 hours postoperatively.
- Patients remain on antibiotics (cephalexin) while the pain catheter is still in place.
- Dressings are removed on the second postoperative day and showering is allowed the following day.
- Patients are seen at 10 days postoperatively for suture removal.
- When to start physical therapy after rotator cuff repair is debated among orthopedic surgeons. The decision is based on the perceived risks and benefits of early motion.
- The major benefit of early motion is the potential limitation of postoperative shoulder stiffness. The main risks include repair disruption and limited healing.
- Early passive motion has historically been recommended after open rotator cuff repair. With the advent of arthroscopic repairs, scarring from soft tissue dissection is minimized, so limiting early motion is possible.
- Limited early motion may improve tendon healing.
- Several factors, including tear size, tendon and bone quality, and preoperative motion, should be considered in this decision.
- With osteoporotic bone or extremely poor tendon quality, limiting motion initially after repair is recommended.
- Preoperative shoulder motion is an important factor in determining the initiation of motion. Earlier motion may be initiated if preoperative motion is limited and requires manipulation or release at the time of repair.
- In general, tear size is the most important factor in determining the timing of postoperative rehabilitation.
- Limiting early motion in patients with larger tears may provide improved healing potential, given that their overall healing rates are much lower than smaller tears.
- Patients with small or medium-sized tears remain in a sling for the first 6 weeks after surgery.
- Elbow and hand range-of-motion exercises are started immediately.
- No shoulder motion is allowed during the first 6 postoperative weeks.
- If there was a significant preoperative motion deficit requiring surgical release or manipulation at the time of repair, early passive motion is allowed.
- After 6 weeks, the sling is removed and patients are started on passive and active assisted range-of-motion exercises, including forward elevation in the scapular plane, external rotation in full abduction, and pendulum and pulley exercises.
- Internal rotation and shoulder extension is limited and patients are instructed not to perform any lifting, pulling, or overhead activity.
- At 3 months after surgery, strengthening exercises are initiated. These begin with isometric exercises and progress to isotonic exercises, with a stretching program maintained throughout.
- Return to sports and full unrestricted activity is allowed at 4 to 5 months.

- For large or massive tears, patients remain in a sling with no shoulder motion for 6 weeks.
- At 6 weeks, the sling is removed and patients are allowed to lift the arm to shoulder height only.
- Formal physical therapy is not initiated at this time. Instead, a shoulder continuous passive motion (CPM) device (Breg Flexmate S500, Breg, Inc., Vista, CA) is used to regain forward elevation in the scapular plane. CPM use is continued until 3 months postoperatively.
- At this time, formal physical therapy is initiated, including passive and active motion and strengthening as per the protocol for small and medium-sized tears.
- Return to sports and unrestricted activities is allowed at 6 months postoperatively.

OUTCOMES

- Functional outcomes after both open and arthroscopic rotator cuff repair have been reported to be durable at long-term follow-up. A number of factors have been correlated with outcomes after repair, including patient age, tear size, tear acuity, workers’ compensation status, preoperative smoking status, muscle quality, and tendon healing.
- Most series reporting outcomes after complete arthroscopic rotator cuff repair are in single-row repairs. The potential advantage of a double-row repair is improved initial repair fixation strength and restoration of the normal anatomic rotator cuff footprint. Improved initial fixation strength and footprint restoration should lead to improved healing rates. In both open and arthroscopic repairs, tendon healing is correlated with improved outcomes. Therefore, double-row repairs may lead to improved clinical outcomes.
- There are limited series reporting the outcomes of complete arthroscopic double-row rotator cuff repairs.
- Suguya et al compared healing rates and outcomes between single- and double-row repairs in 78 patients an average of 35 months after surgery using MRI. There were significant improvements in UCLA and American Shoulder and Elbow Surgeons (ASES) scores in both repair groups, with no significant difference found between techniques. There was a significant increase in retear rates with single-row repairs.
- Andersson et al recently evaluated 48 patients at a mean of 30 months after double-row repair with ultrasonography. There was a significant improvement in active motion, strength, and outcomes when compared to preoperative values. The overall retear rate was 17%, with no significant difference in outcomes between healed and retorn tendons. Healed shoulders were significantly stronger in elevation and external rotation.
- Overall, double-row repairs appear to have improved healing rates compared to single-row repairs, although functional results are very similar.

COMPLICATIONS

- Several factors can be directly correlated with persistent pain and limited function after repair.
- These factors are broken down into three categories: surgeon-controlled, non-surgeon-controlled, and patient-related factors.
- They include incorrect or incomplete diagnosis, surgical technical error, stiffness, infection, and anesthesia-related complications.
Infection after rotator cuff repair is uncommon.

Continued pain after rotator cuff repair can often occur if a second pathology is not identified and treated.

- Conditions often confused with rotator cuff disease include cervical spine disorders, suprascapular neuropathy, acromioclavicular joint arthritis, biceps tendinopathy, glenohumeral instability or arthritis, labral tears, and frozen shoulder.
- A complete history and physical examination can prevent missing several of these problems, which can often be treated concomitantly at the time of rotator cuff repair.
- Technical problems leading to persistent pain and dysfunction after repair can be grouped into repair failures, deltoid detachment, neurologic injury, excess fluid extravasation, and patient positioning injuries.
- The most likely reason for failure of tendon healing after repair is patient age.
- Poor surgical technique, including poor knot-tying, limited fixation (number of anchors), and poor anchor insertion technique, can all lead to a weak biomechanical construct.
- Deltoid detachment is avoided in the setting of complete arthroscopic repair, but if a mini-open approach is performed, then excess detachment without bony repair can lead to failure of healing.
- Transient neurologic injury can occur secondary to excess traction when the lateral position is used.
- Proper portal placement is critical to avoid axillary (posterior and lateral portals) and musculocutaneous (anterior portal) nerve injury.
- Excess swelling due to fluid extravasation into the deltoid can significantly raise intramuscular pressures. Therefore, pump pressures should be kept below 50 mm Hg, with procedure times less than 2 hours.
- Proper padding around the knees (lateral position) and flexing the hips and knees (beach-chair position) can avoid iatrogenic problems secondary to positioning.
- Postoperative stiffness is another potential complication.
  - With limited surgical dissection associated with complete arthroscopic repairs, the risk of stiffness may be significantly reduced when compared with open repairs.
  - While overall rates of postoperative stiffness have not been clearly reported, more than 5% to 10% of open repairs are complicated by either adhesions in the humeral scapular interface or capsular contracture.
  - We now routinely hold all shoulder motion after arthroscopic repairs for several weeks in an attempt to improve healing rates, with limited concern for developing postoperative stiffness.
  - If significant stiffness does develop that is resistant to therapy, arthroscopic lysis of adhesions in the subacromial space along with capsular release is recommended.
  - Infection after rotator cuff repair is uncommon.
    - Most series report infection rates of 1% to 2% after open or mini-open rotator cuff repairs.
    - While there are few reported studies of infection rates after complete arthroscopic repairs, it appears that infection is less common than after open or mini-open repairs.
    - Diagnosis is often delayed in cases of postoperative infection, and persistent wound drainage is the most consistent examination finding.
    - Cultures will often grow Propionibacterium acnes, Staphylococcus aureus, and coagulase-negative Staphylococcus aureus.
    - P. acnes often takes 7 to 10 days to grow on cultures. Therefore, cultures should be held in the setting of postoperative infections for at least 1 week.
    - Treatment consists of multiple debridements and intravenous antibiotics for usually 6 weeks.
    - Outcomes after infection are satisfactory, although significant delays in diagnosis or treatment can lead to inferior results.
  - Anesthetic complications can occur after rotator cuff repair.
    - If general anesthesia is used, major complications occur less than 1% of the time.
    - More commonly, nausea, inability to void, and severe pain are the complications seen in the setting of outpatient elective shoulder surgery.
    - If an interscalene block is used, inadequate anesthesia is the most common complication.
    - Temporary Horner syndrome, phrenic nerve paralysis, and recurrent laryngeal nerve block are common but usually without significant consequence.
    - Intraneural injection or needle injury to the nerve roots can occur.
    - Symptoms such as persistent paresthesias or numbness can be irritating but usually resolve with time (possibly several months).

**REFERENCES**

DEFINITION
- A subscapularis tendon tear typically occurs at its insertion into the lesser tuberosity of the proximal humerus.
- Although the subscapularis is the largest of the rotator cuff muscles, historically it has received little attention.
- Subscapularis tendon tears are often overlooked and under-diagnosed; therefore, a proper evaluation of the shoulder is of paramount importance.
- Treatment of subscapularis tendon tears can restore the functional stability of the shoulder.

ANATOMY
- The subscapularis muscle originates from the medial two thirds of the anterior scapular fossa. The muscle courses laterally beneath the coracoid and becomes tendinous at the glenoid rim. The subscapularis tendon becomes confluent with the glenohumeral joint capsule deep to it and inserts into the lesser tuberosity of the proximal humerus (FIG 1).
- The normal subscapularis tendon not only intermingles with the fibers of the glenohumeral joint capsule deep to it, but at its insertion it also intermingles with the fibers of the medial sling of the long head of the biceps tendon. The medial sling is composed of fibers from the superior glenohumeral ligament and the coracohumeral ligament complex.
- The tendon insertion is about 2.5 cm long (range 1.5 to 3.0 cm) and is trapezoidal, with the widest portion at its most superior (cephalad) aspect.
- The superior aspect also happens to be the strongest part of the subscapularis insertion.

PATHOGENESIS
- As with the other rotator cuff tendons, intrinsic factors may play a role in the development of a subscapularis tendon tear. Furthermore, extrinsic mechanical factors have also been implicated in the process.
- The normal subcoracoid space (coracohumeral interval) represents the distance from the coracoid tip to the proximal humerus. If this space is stenotic, the coracoid tip will impinge against the insertion of the subscapularis, causing damage to the tendon insertion.
- Anatomic and imaging studies have defined the normal coracohumeral interval to be between 8.4 mm and 11 mm.
- Subcoracoid stenosis is defined as less than 6 mm of space between the coracoid and the proximal humerus (either by magnetic resonance imaging [MRI] or arthroscopy).
- Patients with subscapularis tears often have a significantly reduced coracohumeral interval (5 mm with subscapularis tears vs. 10 mm without subscapularis tears).
- In subcoracoid impingement, the coracoid abuts against the anterior surface of the subscapularis, causing increased articular (under) surface tensile forces that can cause tendon fiber failure.
- Two separate cadaveric studies found that subscapularis tendon tears are often partial-thickness articular tears. Furthermore, they usually begin at the superior aspect of the insertion and are common in the elderly population.
- However, complete tears of the subscapularis tendon often result in medial retraction of the tendon edge to the level of the glenoid.
- The retracted tendon often pulls with it the adjacent medial sling of the biceps tendon (composed of fibers from the superior glenohumeral ligament and coracohumeral ligament).
- The fibers of the medial sling are oriented approximately perpendicular to the fibers of the subscapularis tendon and arthroscopically appear as a comma-shaped soft tissue structure that we refer to as the “comma sign” (FIG 3).
We have found the “comma sign” to be a useful guide for identifying the retracted superolateral edge of the subscapularis tendon.

The loss of the subscapularis tendon results in an unstable glenohumeral fulcrum and abnormal glenohumeral arthrokinematics.\(^{12}\)

### NATURAL HISTORY

- There is little available information on the natural history of subscapularis tendon tears.
- In some patients (especially those with massive rotator cuff tears) the tears can be disabling. Some patients with massive rotator cuff tears never regain functional overhead use of their arms without surgical intervention.

### PATIENT HISTORY AND PHYSICAL FINDINGS

- Although most subscapularis tears in the community are degenerative in nature, the classic scenario for a traumatic tear is forced external rotation.
- Forced external rotation results in an eccentric tensile load, which can be particularly dangerous to a “tendon at risk.”
- In contrast to patients with the typical posterosuperior rotator cuff tear, who have difficulty with overhead tasks, patients with subscapularis tears often have the burden of diminished function with tasks in front of the body and below the level of the shoulder.
- The typical patient complains of chronic pain and loss of arm strength with activities of daily living in front of the body.
- A complete physical examination is necessary, including examination of the cervical spine and both upper extremities. Examinations to perform are:

---

**FIG 2** • Schematic drawing of the roller-wringer effect. In patients with subcoracoid impingement, the prominent coracoid tip indents the superficial surface of the subscapularis tendon. This creates tensile forces on the convex, articular surface of the subscapularis tendon and can lead to failure of the subscapularis fibers. \(C\), coracoid; \(H\), humerus. (From Burkhart SS, Lo IKY, Brady PC. A Cowboy’s Guide to Advanced Shoulder Arthroscopy. Philadelphia: Lippincott Williams & Wilkins, 2006.)

**FIG 3** • **A,B.** Anterior structures from a posterior viewing portal of a right shoulder. The medial sling (\(M\)) of the biceps tendon (\(BT\)) inserts into the lesser tuberosity of the humerus (\(H\)) along with the superolateral margin of the subscapularis (\(SSc\)). **C,D.** Complete subscapularis tendon tear. In this situation, the comma sign (\(,\)) leads to the superolateral border of the subscapularis tendon. \(G\), glenoid; \(C\), coracoid. (From Burkhart SS, Lo IKY, Brady PC. A Cowboy’s Guide to Advanced Shoulder Arthroscopy. Philadelphia: Lippincott Williams & Wilkins, 2006.)
We also routinely obtain an MRI of the affected shoulder.

■ 30-degree caudal tilt, outlet view, and axillary plain films.

We routinely obtain five views of the shoulder: anteroposterior (AP) internal rotation, AP external rotation, AP with 30-degree caudal tilt, outlet view, and axillary plain films.

Evaluation of the plain films may reveal proximal humeral migration (especially with longstanding massive rotator cuff tears), acromial morphology, glenohumeral or acromioclavicular joint degenerative changes, anterior humeral translation (seen with subscapularis tendon disruptions on the axillary view), and so forth.

We also routinely obtain an MRI of the affected shoulder.

■ The MRI can provide important information on the location and extent of the subscapularis tendon tear.

■ It can also determine whether additional pathology in the shoulder coexists (eg, additional rotator cuff tears, medial subluxation or tears of the long head of the biceps tendon, ganglion cysts, labral tears).

■ Tears of the subscapularis tendon are best appreciated on the axillary images of the MRI (Fig 4).

Signal characteristics consistent with fluid may be seen with partial-thickness tears, whereas a loss of part or all of the normal tendon will be seen with full-thickness tears.

DIFFERENTIAL DIAGNOSIS

■ Subscapularis tendinitis or bursitis

■ Posterosuperior rotator cuff tear

■ Biceps tendinitis

■ Labral tear

■ Neurologic impairment

NONOPERATIVE MANAGEMENT

■ The role of nonoperative treatment in patients with symptomatic subscapularis tears is very limited.

■ Most patients who present to orthopedic surgeons with subscapularis tears have had the tear for a long time.  

■ Furthermore, most have attempted and failed nonoperative treatment.

■ However, for patients who are not good surgical candidates (eg, very old, ill), nonoperative treatment is warranted.

■ Nonoperative treatment typically consists of activities as tolerated with gentle stretching and progressive strengthening of the shoulder.

SURGICAL MANAGEMENT

Preoperative Planning

■ The history, physical examination, plain films, and MRI should all be reviewed before operative intervention.

Positioning

■ The anesthesiologist administers general anesthesia with endotracheal intubation and applies protective eyewear to the patient.

■ The patient is rotated into the lateral decubitus position and an axillary roll is placed.

■ The patient is well padded with pillows beneath and between the legs.
- The patient is secured in place with a vacuum beanbag and is tilted back approximately 10 degrees.
- A warming blanket is applied to prevent hypothermia.
- The sterile field must extend posteriorly to a position medial to the scapula and anteriorly just lateral to the nipple.
- After the patient is properly protected, positioned, padded, and draped, the surgeon performs an examination under anesthesia.
- The assistant prepares the operative extremity with a sterile scrub.
- The arm is then placed in 5 to 10 pounds of balanced suspension (Star Sleeve Traction System; Arthrex Inc., Naples, FL) with the shoulder in 20 to 30 degrees of abduction and 20 degrees of forward flexion (FIG 5).

**Approach**

- Successful treatment of subscapularis tears has been documented with both open and arthroscopic techniques.
- We prefer and will present our arthroscopic technique for treatment of a subscapularis tendon tear.

**PORTALS AND VISUALIZATION**

- The surgeon should remember the “6 Ps” for arthroscopic portals: “Proper portal placement prevents poor performance.”
- Our standard posterior viewing portal is placed 4 to 5 cm inferior (caudal) to the posterior border of the acromion and 3 to 4 cm medial to the posterolateral corner of the acromion (TECH FIG 1A).
- A standard diagnostic arthroscopy of the entire glenohumeral joint is performed.
- To fix the tear one must be able to see the tear. This point cannot be emphasized enough, and throughout the procedure special attention is paid to optimize visualization by controlling bleeding.
  - Key factors include minimizing the pressure differential between the patient’s blood pressure and the arthroscopic pump pressure; making use of the Bernoulli principle to achieve turbulence control; and using electrocautery as needed to cauterize specific bleeding points.
- The subscapularis tendon presents a unique problem to visualization. The tendon tear is often in a very confined space that may be unfamiliar to the surgeon (TECH FIG 1B). This space can become even more constricted with soft tissue swelling as the case proceeds, so we recommend repairing the subscapularis tendon before addressing any other problems in the shoulder.
- We have found that examination of the subscapularis tendon for a partial tear is optimized with shoulder flexion and internal rotation (lifts the subscapularis tendon off its footprint on the lesser tuberosity; TECH FIG 1C).
- Visualization is further enhanced with a “posterior lever push” in which an assistant pushes the proximal humerus posteriorly while pulling the distal humerus anteriorly (TECH FIG 1D).
- A 70-degree arthroscope is an extremely helpful additional tool that can improve visualization by providing an “aerial view.”
  - The initial identification and orientation should be done with a 30-degree arthroscope, however, because it is easy to get lost and stray dangerously inferior into the vicinity of neurovascular structures if the 70-degree arthroscope is used initially.
- The primary working portal is the anterosuperolateral portal, which is 1 to 2 cm lateral to the anterolateral corner of the acromion.
  - An 18-gauge spinal needle is introduced into the glenohumeral joint to make a 10-degree angle of approach to the lesser tuberosity.
  - Advantages of the anterosuperolateral portal include a good angle of approach to prepare the lesser tuberosity bone bed; a near-parallel angle of approach to the subscapularis for mobilization and antegrade suture passage; and an angle of approach to the coracoid tip that will allow a coracoplasty to be made in a plane that is parallel to the subscapularis tendon.
  - The next portal created is the anterior portal, which is 4 to 5 cm inferior to the anterior acromion, just lateral to the coracoid tip.
  - An 18-gauge spinal needle is introduced into the glenohumeral joint to determine a 45-degree angle of approach to the lesser tuberosity, and then the portal is established in that line of approach.
- Advantages of the anterior portal include an optimal angle of approach for anchor placement, suture management, and on occasion retrograde suture passage (although we almost always do antegrade suture passage through the subscapularis tendon via an anterosuperolateral portal).
Subscapularis tendon tears are often associated with tearing or medial subluxation of the long head of the biceps tendon. The long head of the biceps tendon should be inspected from its base to the intertubercular groove. It is often helpful to pull the tendon into the glenohumeral joint and to pay particular attention to the medial surface of the tendon for partial tearing.

Also, internal and external rotation of the humerus may reveal subluxation of the tendon. The biceps tendon should never pass posterior to the plane of the subscapularis with rotation of the humerus.

Most of our patients with biceps tendon tearing or subluxation in association with a torn subscapularis receive a biceps tenodesis.

In our view the alternatives are suboptimal:

- Biceps tendon subluxation left alone will result in increased stress to the subscapularis repair and may ultimately cause it to fail.
- Significant biceps tendon degeneration may result in continued shoulder pain and dysfunction.

BICEPS TENDON

- Biceps tenotomy has been shown in the literature to result in decreased elbow flexion and forearm supination strength, and some patients consider it aesthetically undesirable. Therefore, we perform a biceps tenotomy only in elderly patients with low demands and poorly defined arm musculature.

The initial step in the tenotomy is to place two half-racking stitches 1 to 2 cm distal to the base of the long head of the biceps tendon (TECH FIG 2). These sutures tighten and lock against the tendon to securely hold it after it is tenotomized (in preparation for tenodesis).

The tenotomy is made at the base of the biceps with electrocautery or scissors. Care is taken not to damage the superior labrum.

The biceps tendon is then extracted extracorporeally through the anterosuperolateral portal. Pushing on the skin around the tendon’s exit point and flexing the elbow and shoulder aids in presenting the tendon out of the portal.

A no. 2 FiberWire (Arthrex) whipstitch is run with three or four passes on each side of the tendon.
The whipstitch sutures are temporarily pulled through the anterosuperolateral portal outside the cannula so that it will be out of the way until it is time to do the biceps tenodesis.

This temporary tenotomy improves subscapularis visualization and working space. At the end of the case, after the subscapularis tendon has been repaired, we prefer to anchor the biceps tendon to bone using the BioTenodesis screw system (Arthrex) to obtain a secure interference fit of tendon against bone.

Subcoracoid Space

The first step in defining the subcoracoid space is to identify the coracoid tip.

- If the subscapularis tendon is intact or partially torn, the coracoid tip is located just anterior to the upper border of the subscapularis tendon. With internal and external rotation of the humerus the coracoid tip can be seen as a moving bulge in the rotator interval.
- Through the anterosuperolateral portal the electrocautery can be used to create a window in the rotator interval tissue to expose the coracoid tip (the surgeon must take care to preserve the medial sling of the biceps tendon).
- If the subscapularis tendon is completely torn and retracted, the coracoacromial ligament is a useful guide to the coracoid tip.
- The surgeon should use an instrument to palpate and confirm the location of the coracoid tip.

We have found that the best method of measuring the coracohumeral interval is direct visualization during arthroscopy with an instrument of known size through the anterosuperolateral portal (eg, the diameter of a shaver blade). Gentle axial distraction may be necessary to obtain an accurate measurement if there is any proximal humeral migration.

We also routinely place the shoulder in the provocative position of flexion, horizontal adduction, and internal rotation to arthroscopically evaluate if there is any impingement between the coracoid tip and the subscapularis tendon and proximal humerus.

If there is any evidence of subcoracoid stenosis (coraco-humeral interval less than 6 mm) or impingement, we perform a coracoplasty with a goal of creating a coraco-humeral interval of 8 to 10 mm.
The soft tissues on the posterolateral surface of the coracoid are removed ("skeletonizing" the coracoid) with electrocautery and a motorized shaver (the surgeon must be careful not to release the conjoint tendon from the undersurface of the coracoid tip; TECH FIG 3A,B).

The fibers of the coracoacromial ligament may be released for improved visualization.

The anterosuperolateral portal provides a great angle of approach for the high-speed burr to be parallel to the subscapularis tendon for the coracoplasty.

A "posterior lever push" may improve the anterior working space by 5 to 10 mm (TECH FIG 3C,D). A second assistant who is anterior to the patient in a lateral decubitus position provides a posterior force to the proximal humerus with a simultaneous anterior force to the distal humerus.

Alternating between the 30- and 70-degree arthroscopes as needed optimizes visualization.

The coracoplasty improves the anterior working space for the subscapularis repair and prevents future abrasion to protect the repair.

**SUBSCAPULARIS MOBILIZATION**

- We routinely perform a three-sided release for complete, retracted subscapularis tendon tears.
- The three-sided release can be difficult secondary to retraction, scarring, and working in a constricted space.
- The surgeon may be concerned about the proximity of neurovascular structures; however, a cadaveric study found that the axillary nerve, axillary artery, musculocutaneous nerve, and lateral cord of the brachial plexus are all more than 25 mm from the coracoid base. The key is to stay on the posterolateral aspect of the coracoid.
- The first step to mobilizing the subscapularis is to place a traction suture at the junction of the superolateral tendon and "comma tissue" (TECH FIG 4A).
- The comma tissue is a comma-shaped fibrous band of tissue at the superolateral border of the subscapularis tendon; its fibers are oriented at right angles to those of the subscapularis. It is the remnant of the medial sling of the biceps after it pulls loose from its footprint on the lesser tuberosity directly adjacent to the footprint of the upper subscapularis.
- This can be done through the anterosuperolateral portal with a Viper or Scorpion suture passer (Arthrex) loaded with a free no. 2 FiberWire suture (Arthrex). The traction suture can then be held outside the cannula to allow continued use of the anterosuperolateral portal.
- The anterior release (subscapularis from the posterolateral coracoid and deltoid fascia) may be done by alternating the electrocautery with the shaver.
- If a coracoplasty was not performed earlier, the soft tissues are removed from the coracoid ("skeletonizing" the posterolateral coracoid; TECH FIG 4B).
- The release is continued medial along the posterolateral coracoid until the subscapularis muscle belly is visible beneath the arch of the coracoid neck and base.
The superior release (subscapularis from the undersurface of the coracoid neck and base) may then be done with a 30-degree arthroscopic elevator (TECH FIG 4C). The release is done only to the midpoint of the undersurface of the coracoid neck (to prevent damage to the neurovascular structures medial to the coracoid neck). The posterior release (subscapularis from the glenoid neck) may then be done with a 15-degree arthroscopic elevator (TECH FIG 4D). The release is continued medial until the subscapularis is freely mobile. The posterior release is the safest release (because it is in a very safe plane between the subscapularis and the coracoid neck and base). The inferior release is the most dangerous and has not been necessary in our experience.

**BONE BED PREPARATION AND ANCHOR PLACEMENT**

- The anterosuperolateral portal has a great angle of approach for removing the soft tissues off the subscapularis footprint of the lesser tuberosity.
- A ring curette may be used to precisely remove the soft tissues up to the articular margin. Then electrocautery is used to ablate any soft tissue on the footprint (TECH FIG 5A).
- The high-speed burr then removes the “charcoal” (residual of electrocauterization) to a bleeding bone bed without decorticating the bone (TECH FIG 5B).
- To decrease the tension at the repair site, we have found that the subscapularis footprint may be medialized up to 5 mm with no detriment to its function.
One anchor should be placed every centimeter, which typically results in one anchor for a partial tear and two anchors for a complete tear (if a single-row repair is done).
- The anchors should be placed in order from inferior (caudal) to superior (cephalad).
- We use double-loaded anchors to reduce the load on each suture.
- The best angle of approach for anchor placement is typically through the anterior portal (TECH FIG 5C).
- The surgeon’s hand and instruments (eg, punch and anchor inserter) are often close to the patient’s face, which is one reason we place protective eyewear on every patient (TECH FIG 5D,E).

**SUTURE PASSAGE AND KNOT TYING**
- We prefer the Viper or Scorpion suture passers (Arthrex) because they allow antegrade suture passage and retrieval (retrograde suture passage is difficult because the coracoid often blocks a good angle of approach).
- One strand of suture is retrieved from the anchor, pulled out the anterosuperolateral cannula, and loaded in the suture passer.
- Tension is placed on the traction suture (which is inside the anterosuperolateral portal but outside its cannula) and the suture is passed about 10 mm from the lateral edge of the subscapularis tendon (TECH FIG 6A).
- For the superior anchor, the sutures should be passed over the top of the superolateral border of the subscapularis, just medial to the “comma tissue.” This will provide a “ripstop” to prevent lateral cutout of the sutures.
- The process is repeated for the second suture of the same anchor.
- Both the sutures are tied through a clear cannula with a double-diameter knot pusher (Surgeon’s Sixth Finger, Arthrex; TECH FIG 6B).
- We use a six-throw arthroscopic surgeon’s knot, which is composed of a static base knot of three stacked half-hitches followed by three reversing half-hitches on alternating posts (TECH FIG 6C).
- The arthroscopic surgeon’s knot with a double-diameter knot pusher has been found in the laboratory to have the best combination of loop and knot security.\(^\text{11}\)
- To maximize efficiency and visualization, we tie the sutures of the inferior anchor before working on the superior anchor (TECH FIG 6D).
- After completing the subscapularis tendon repair we internally and externally rotate the humerus to be sure that we have achieved secure apposition of the tendon against the bone.
**POSTOPERATIVE CARE**

- An arthroscopic subscapularis tendon repair is usually an outpatient procedure.
- After the arthroscopic portals are closed, a sterile dressing is applied over the shoulder.
- A sling with a small pillow is applied with the arm at the side. The sling is worn full-time for 6 weeks, except when bathing or eating.
- During the first 6 weeks the patient should perform daily active wrist and elbow motion.
  - The patient must not externally rotate past neutral (straight-ahead position) for 6 weeks.
  - There is no overhead motion in the first 6 weeks.
  - At 6 weeks from the operation the sling is discontinued.
  - The patient is started on a passive stretching program that includes passive external rotation with a cane up to 45 degrees and overhead stretches with a rope and pulley.
  - At 12 weeks from the operation the patient is started on a strengthening program with elastic bands.
  - If the subscapularis tear is part of a massive anterosuperior rotator cuff tear, then strengthening is delayed until 16 weeks postoperatively.
  - Progression to light weights is based on the patient’s progress.
  - Rehabilitation focuses on strengthening the scapular stabilizers and deltoid and rotator cuff muscles.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Diagnosis</th>
<th>A complete history, a proper physical examination, full evaluation of the diagnostic studies, and a thorough arthroscopic evaluation of the shoulder are necessary.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Portal placement</td>
<td>Proper portal placement is imperative to achieve the correct angle of approach to work in the subcoracoid space.</td>
</tr>
<tr>
<td>Visualization</td>
<td>The key principles include minimizing pressure differentials (hypotensive anesthesia with adequate arthroscopic pump pressure), avoiding turbulence, using the posterior lever push, and using both the 30- and 70-degree arthroscopes freely.</td>
</tr>
<tr>
<td>Secure fixation</td>
<td>The subscapularis tendon must be securely apposed to the bone to optimize healing. Important biomechanical principles include the proper angle of insertion of the suture anchors; use of double-loaded anchors to reduce the load on each suture; use of strong sutures; proper suture placement in the tendon; and optimized loop and knot security.</td>
</tr>
<tr>
<td>Rehabilitation</td>
<td>The patient must clearly understand what he or she can do to protect and optimize healing of the subscapularis tendon repair.</td>
</tr>
</tbody>
</table>
Return to full, unrestricted activities is usually at 6 to 12 months and is based on the patient, the size of the tear, the strength of the repair, and the patient’s rehabilitation progress.

**OUTCOMES**

- The results after arthroscopic subscapularis tendon repair have been quite favorable.²,³,⁹
- The senior author (SSB)³ published his preliminary results in 2002.
- In this series of 25 consecutive patients with a mean follow-up of 11 months, 92% had good or excellent results by the UCLA criteria.
- There was a significant improvement in pain and functional motion.
- Eight of ten patients who had proximal humeral migration preoperatively had reversal of the migration and functional overhead use of their arm.
- Bennett² also found encouraging results in his prospective cohort with 2- to 4-year follow-up.
- The patients had a mean American Shoulder and Elbow Surgeons (ASES) score improvement from 16 preoperatively to 74 postoperatively.
- Visual analogue pain scores improved from 9 preoperatively to 2 postoperatively.
- Kim et al,⁹ in a recent report of patients who had an arthroscopic repair of isolated partial articular-sided tears, found similar improvements in pain and function.
- At a mean follow-up of 27 months, UCLA scores improved from 23 preoperatively to 33 postoperatively, ASES scores improved from 67 to 96, and visual analogue pain scores improved from 5 to 0.3.

**COMPLICATIONS**

- Stiffness
- Retear
- Neuropraxia
- Infection

**REFERENCES**

DEFINITION

- About 9% of shoulder girdle injuries involve damage to the acromioclavicular (AC) joint.
- This is a sequential injury beginning with the AC ligaments, progressing to the coracoclavicular ligaments, and finally involving the deltoid and trapezial muscles and fascia.
- Patients usually report direct trauma to the lateral shoulder or a fall on an outstretched arm driving the humeral head into the AC joint, resulting in a dislocation with pain at the AC joint, in particular with cross-arm adduction.
- Dislocations are classified by severity of injury, radiographic findings, and position of the clavicle (Table 1).

ANATOMY

- The AC joint is a diarthrodial joint that primarily rotates as well as translates in the anteroposterior as well as the superoinferior plane.
- The scapula (acromion) can protract and retract, using the AC joint as a pivot point.
- Normal scapular motion consists of substantial rotations around three axes and plays a major role in the motion at the AC joint.
- The articular surface is made up of hyaline cartilage containing an intra-articular meniscus type of structure, all surrounded by a joint capsule with a synovial lining.
- The AC joint static stabilizers include the acromioclavicular ligaments (superior, inferior, anterior, and posterior), the coracoclavicular ligaments (trapezoid and conoid), and the coracoclomial (CA) ligament.
- The AC joint dynamic stabilizers consist of the deltoid and trapezius muscles.
- Appreciating the location of the coracoclavicular ligament attachment on the clavicle is important. The trapezoid attach to the undersurface of the clavicle at an anterolateral position. The conoid is a broad stout ligament located in a posterior and medial position. Both the trapezoid and conoid are posterior to the pectoralis minor attachment on the coracoid. (FIG 1).
- The AC joint capsule and the capsular ligaments are the primary restraints of the distal clavicle to anterior-to-posterior translation. More specifically, the superior and posterior AC capsule ligaments prevent posterior displacement of the clavicle and abutment against the scapular spine.
- The trapezoid and conoid span the coracoclavicular space (1.1 to 1.3 cm) and contribute to vertical stability, preventing superior and inferior translation of the clavicle.
- The AC and coracoclavicular ligaments all contribute to the prevention of motion in all planes. The conoid ligament has the highest in situ forces with superior loads, regardless of the integrity of the AC ligaments. The AC ligaments are the main restraints to posterior and anterior translation. However, when the AC ligaments are transected, the conoid is the primary restraint to anterior loads and the trapezoid is the primary restraint to posterior loads.
- The AC joint is innervated by the lateral pectoral nerve and the suprascapular nerve.

PATHOGENESIS

- The mechanism of most AC joint injuries is a direct blow to the lateral acromion with the arm adducted.
- Indirect injury occurs by falling on an adducted outstretched hand or elbow, causing the humeral head to translocate superiorly and drive the humeral head into the acromion.

NATURAL HISTORY

- Most patients with type I or II AC joint separations typically have full recovery with no long-term sequelae. However, some patients continue to be symptomatic. In one study, up to 27% of patients with type I and II injuries had persistent pain and required a surgical procedure. Some patients treated nonoperatively continued to have instability and pain with provocative tests (level IV evidence).
- Most patients with type III separations do well with conservative treatment. In a survey of Major League Baseball team physicians, 80% of athletes treated nonoperatively had complete pain relief and normal function (level IV evidence). Studies have failed to show a statistical difference in the return to activity (level IV evidence).
- Type IV, V, and VI AC joint separations do poorly without operative intervention (level V evidence).
- Persistent pain is attributed to a chronically dislocated AC joint with severe soft tissue disruption.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The mechanism of injury is an important history finding that clues one into a possible AC joint injury.
- Pain at the AC joint is difficult to differentiate from glenohumeral pathology because of the dual innervation of the AC joint by the lateral pectoral nerve and suprascapular nerve.
- Because of the innervation by the lateral pectoral nerve, some patients may present with anteromedial pain, further complicating the picture.
- Pain in the trapezius region and anterolateral deltoid is more specific for AC joint injury, whereas pain located only in the lateral deltoid is more indicative of a subacromial process.
- Pathology of the AC joint is identified by a triad of point tenderness, positive pain at the AC joint with cross-arm adduction, and relief of symptoms by injection of a local anesthetic.
- Methods for examining the AC joint include the following:
  - AC joint compression (shear) test: Isolated painful movement at the AC joint in conjunction with a history of direct trauma indicates AC joint pathology.
  - Cross-arm adduction test: Look for pain specifically at the AC joint. Pain at posterior aspect of shoulder or lateral shoulder might indicate other pathology.
Chapter 12  REPAIR AND RECONSTRUCTION OF ACROMIOCLAVICULAR INJURIES 103

Paxinos test\(^\text{16}\) is sometimes done in conjunction with bone scan to assess damage to AC joint.

O’Brien test: Symptoms at the top of the joint must be confirmed by examiner palpating the AC joint. Anterior glenohumeral joint pain suggests labral or biceps pathology.

Local point tenderness at the AC joint while keeping the glenohumeral joint still is suspicious for localized AC joint pathology.

---

**Table 1  Classification of Acromioclavicular (AC) Joint Injuries**

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
<th>Inspection</th>
<th>Radiographic</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Sprain of the AC joint with all ligaments intact. Mechanism of injury consistent with AC joint injury. No evidence of instability.</td>
<td>Point tenderness at the AC joint and positive provocative tests. Radiographs are normal.</td>
<td></td>
</tr>
<tr>
<td>II</td>
<td>Rupture of AC ligaments. Sprain of coracoclavicular (CC) ligaments.</td>
<td>Mild subluxation of the AC joint can be observed with stress examination. Radiographs of the lateral end of the clavicle may be slightly elevated, but stress views fail to show a 100% separation of the clavicle and acromion.</td>
<td></td>
</tr>
<tr>
<td>III</td>
<td>Complete disruption of both the AC and CC ligaments without significant disruption of the deltoid or trapezial fascia. The clavicle is unstable in both the horizontal and vertical planes.</td>
<td>The upper extremity is usually held in an adducted position with the acromion depressed while the clavicle appears high-riding, but in reality the acromion and the rest of the upper extremity is displaced inferior to the horizontal plane of the lateral clavicle. Radiographs show up to 100% increase in the CC interspace.</td>
<td></td>
</tr>
<tr>
<td>IV</td>
<td>Complete disruption of both the AC and CC ligaments.</td>
<td>The distal clavicle is posteriorly displaced into the trapezius muscle and may tent the posterior skin. Evaluation of the sternoclavicular (SC) joint is necessary to rule out anterior SC joint dislocation. Posteriorly displaced clavicle can be seen on axillary view, which is always obtained in the standard radiographic evaluation of the AC joint.</td>
<td></td>
</tr>
<tr>
<td>V</td>
<td>AC and CC ligaments are disrupted.</td>
<td>Severe droop secondary to anteroinferior translation of the scapula around the thorax, due to the weight of the arm and the geometry of the chest wall. This is considered the third translation of the scapula with loss of the clavicular strut. Reduction of the distal clavicle with shoulder shrug differentiates type III from type V (distal clavicle buttonhole through soft tissue sleeve). Trapezial and deltoid fascia disrupted. Two to three times increase in the CC distance or a 100% to 300% increase in the clavicle-to-acromion radiographic distance.</td>
<td></td>
</tr>
<tr>
<td>VI</td>
<td>Inferior dislocation of distal clavicle. Reduction may be blocked from interposition of the intact posterosuperior AC ligaments within the AC interval. Mechanism is thought to be severe hyperabduction and external rotation of the arm combined with retraction of the scapula.</td>
<td>The distal clavicle is found in two orientations, either subacromial or subcoracoid, behind the intact conjoined tendon.</td>
<td></td>
</tr>
</tbody>
</table>

---

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standard radiographs include AP, supraspinatus outlet view (FIG 2A), and axillary and Zanca views.
- A Zanca view is made by tilting the x-ray beam 10 to 15 degrees toward the cephalic direction (FIG 2B,C).
- The AC joint is more superficial and surrounded by less soft tissue than the glenohumeral joint.
The AC joint may be better visualized if a reduced penetration strength is used compared to standard radiographs of the glenohumeral joint.

An axial view of the shoulder is important in differentiating a type III from a type IV AC joint injury.

Coracoid base fractures can also be identified on this view.

A normal coracoclavicular interspace, in conjunction with a complete dislocation of the AC joint, may indicate a coracoid fracture, in which case a Stryker notch view is helpful (FIG 2D).

The AC joint width is normally 1 to 3 mm and decreases with age. The width seen on radiographs is influenced by the individual variability of obliquity of the joint in relation to the x-ray beam.

An increase in the coracoclavicular distance (usually 1.3 cm) of 25% to 50% over the normal side indicates complete coracoclavicular ligament disruption.

Although seldom necessary and mainly a historical practice, stress views (5 to 10 pounds placed in the ipsilateral hand) with increased coracoclavicular interspace on the AP view may help differentiate between type II and type III injuries.

Bone scan may help confirm subtle AC joint pathology and arthrosis.

Differential Diagnosis

- Cervical spine pathology
- Trapezial spasm
- Scapular dyskinesia
- Hyperlaxity
- Distal clavicle or acromion fracture
- Coracoid fracture

**FIG 1**

A. Anterior view. The trapezoid is anterolateral, whereas the conoid is a posteromedial structure.

B. Posterior view. The conoid can be seen as a broad ligament that fans out, attaching to the clavicle in a posteromedial position.

**FIG 2**

Positioning for radiographic studies.

A. Supraspinatus outlet view.

B, C. Zanca view. For optimal visualization of the acromioclavicular joint, the x-ray source is directed 10 degrees cephalad with reduced penetration strength compared to a standard radiograph.

D. Stryker notch view. This view helps rule out concomitant injuries. It is helpful when a coracoid fracture is suspected with a normal coracoclavicular interspace.
Glenohumeral pathology (impingement, rotator cuff, Hill-Sachs, Bankart, superior labral anterior posterior [SLAP] lesion, biceps)

Ulnar paresthesias

Thoracic outlet syndrome

NONOPERATIVE MANAGEMENT

The main goals of treatment, whether surgical or nonsurgical, are to achieve a pain-free shoulder with full range of motion and strength and no limitations in activities.

Most type I and type II AC joint separations are treated in a nonoperative fashion.

Treatment begins with a sling, ice, and a brief period of immobilization only for pain control. Rehabilitation is started as soon as tolerated.

The rehabilitation program consists of four phases:
- Pain control, immediate protective range of motion and isometric exercises
- Strengthening exercises using isotonic contractions
- Unrestricted functional participation with the goal of increasing strength, power, endurance, and neuromuscular control
- Return to activity with sports-specific functional drills

Surgical intervention should be considered after rehabilitation if pain persists for greater than 3 months.

Type III injuries:
- These patients are usually evaluated on a case-by-case basis, taking into account hand dominance, occupation, heavy labor, position and sport requirements (quarterbacks, pitchers), scapulothoracic dysfunction, and risk for re-injury.
- In a meta-analysis of 1172 patients, 88% of those treated with surgery and 87% of those treated without surgery had satisfactory outcomes (level IV evidence).
- In patients with type III injuries treated nonoperatively versus operatively, there was no difference in strength at 2 years of follow-up (level IV evidence).
- Schlegel and Burks found that only 20% of patients reported a suboptimal outcome with conservative care. Objective studies showed that patients had no limitation of shoulder motion in the injured extremity and no difference compared with the unaffected extremity in rotational shoulder muscle strength. A finding that may affect heavy laborers was a decrease of 17% in bench press strength at the 1-year follow-up (level IV evidence).
- If symptoms persist for greater than 3 months, including increased pain, impingement due to scapular dyskinesia, decreased strength, inability to get the arm into a cocking position in throwing, and painful instability, especially posterior instability with the clavicle abutting the anterior portion of the spine of the scapula, then operative intervention may be indicated.

SURGICAL MANAGEMENT

Again, the main goals of treatment, whether surgical or nonsurgical, are to achieve a pain-free shoulder with full range of motion and strength and no limitations in activities.

Complete AC joint injuries (type IV, V, and VI) are usually treated operatively because of the significant morbidity associated with persistently dislocated joints and severe soft tissue disruption.

Most surgeons will treat type III injuries conservatively for 12 weeks and consider surgical stabilization if persistent pain and instability exist. In an attempt to return an athlete or high-demand patient to work more rapidly, some will stabilize a type III separation, hoping to decrease painful instability.

Some patients treated nonoperatively will have persistent pain and an inability to return to their sport or job and will require surgical stabilization.

Operative choices:
- AC ligament repair
- Dynamic muscle transfer
- CA ligament transfer
- Coracoclavicular ligament repair
- Distal clavicle resection with coracoclavicular reconstruction
- Distal clavicle resection without coracoclavicular reconstruction
- Anatomic reconstruction of the coracoclavicular ligament
- Arthroscopic variations of the above

In the treatment of chronic AC joint pain with distal clavicle resection, arthroscopy of the glenohumeral joint can be undertaken to rule out concomitant injuries. Missed SLAP lesions and labral pathology have been reported as a cause of failed distal clavicle resection.

The modified CA ligament transfer (Weaver-Dunn) is the gold standard of treatment for the reconstruction of the AC joint and is presented here.

Anatomic reconstruction of the coracoclavicular ligaments (ACCR) attempts to recreate the normal anatomy and biomechanics of the AC joint. This technique has been studied in our biomechanics laboratory and is in clinical trials. The ACCR is our procedure of choice and is also presented here.

Various arthroscopic techniques have been described for fixation of AC separations.
- A description of an arthroscopic procedure using a high-strength suture and endobutton device is provided.
- Although our preferred treatment of acute type III injuries is conservative, this technique may be helpful for surgeons who decide to stabilize and splint acute type III injuries in high-demand patients.

Preoperative Planning

A successful outcome depends on reasonable patient expectations and compliance with the postoperative regimen, including postoperative sling immobilization for 6 weeks.

All radiographs are reviewed.

Reports indicate that concomitant injuries such as SLAP lesions and labral tears are a cause of failure after distal clavicle resection.

Magnetic resonance imaging (MRI) may be obtained to rule out concomitant injuries that also need to be addressed.

If using a modified Weaver-Dunn or ACCR, the surgeon should discuss with the patient the options for autograft or allograft.

Positioning

The patient is placed in the beach-chair position after induction of general anesthesia (FIG 3).

A specialized shoulder table is not used. We prefer a standard table that provides posterior support and stabilization of the scapula.

A small bump is placed on the medial scapular edge to stabilize it and elevate the coracoid anteriorly.
The head is mobile because repositioning is sometimes necessary during medial clavicle drilling. Wide draping is done to expose the sternoclavicular joint and posterior clavicle for complete visualization of the shoulder girdle. The arm is free draped to allow free motion and reduction.

The mean length from the end of the clavicle, or the AC joint, to the coracoclavicular ligaments is $46.3 \pm 5$ mm; the distance between the trapezoid laterally and the conoid medially is $21.4 \pm 4.2$ mm.\textsuperscript{11}

In both the Weaver-Dunn and ACCR procedures, the incision is made to allow exposure of the AC joint and coracoid. The incision for the Weaver-Dunn is more lateral compared to the ACCR because of the exposure necessary for CA ligament acquisition and because the ACCR clavicle preparation is performed slightly more medially.

Again, full exposure of the AC joint and coracoid is necessary in both procedures, and the incision can be extended or curved to allow the necessary exposure.

Although the AC joint and clavicle are superficial structures with little subcutaneous tissue, in our experience large skin flaps can be used to improve visualization without compromising the vascularity of the skin.

Full-thickness flaps of the deltotrapezial fascia during the approach are critical for closure. Tagging sutures can be placed during the approach to allow for quick and effective soft tissue coverage over the repair.

Gelpi retractors are low profile and help retract the deltotrapezial flaps.

Arthroscopy of the glenohumeral joint can be performed to look for concomitant injuries. An incision is made 3.5 cm from the AC joint starting at the posterior clavicle in a curvilinear fashion toward the coracoid along the lines of Langer. The incision is sometimes angled because the key is to have full visualization of the AC joint laterally and the coracoid process medially (TECH FIG 1).

Superficial skin bleeders are controlled down to the fascia of the deltoid with a needle-tip Bovie. Full-thickness flaps are made from the midline of the clavicle both posteriorly and anteriorly, skeletonizing the clavicle.

Tagging sutures are placed in the deltotrapezial fascia. Traction on the tagging sutures or a Gelpi retractor under the flaps is used for visualization. The tagging sutures are used for easy and precise closure of the fascia at the end of the procedure.

Once the approach is complete, a trial reduction is attempted. The distal end of the clavicle may need to be freed from the trapezius muscle, under the acromion, or coracoid. Interposition of soft tissue may prevent anatomic reduction of the AC joint.

A semitendinosus allograft or autograft or an anterior tibialis allograft can be used for this procedure (TECH FIG 2A). (See the Techniques section of Chap. SM-32 for a description of obtaining a semitendinosus autograft.)

A curvilinear incision is made 3.5 cm medial to the acromioclavicular joint along the lines of Langer. Visualization of the acromioclavicular joint as well as the coracoid is possible. The deltotrapezial fascia is split along the midline of the clavicle and elevated as two full-thickness flaps.
Chapter 12 REPAIR AND RECONSTRUCTION OF ACROMIOCLAVICULAR INJURIES

TECH FIG 2 • A. Grafts need tendon-grasping sutures at both ends for ease of passage around the coracoid and through bone tunnels. B. In our alternative method, grafts that are to be fixed to the coracoid are folded so that there is one short limb and one long limb. A no. 2 nonabsorbable suture is placed through the doubled-over tendon graft in a Krakow manner. Tendon ends are bulleted for ease of passage through bone tunnels.

TECH FIG 3 • A. The graft is looped around the coracoid. B. A suture passer can be used to safely loop the graft and a nonabsorbable suture around the coracoid base. C. In the alternative technique, a bone tunnel that approximates the diameter of the graft (usually 6 to 7 mm) is made in the coracoid. One limb of the Krakow suture is placed, and the doubled-over tendon is passed through the PEEK screw and driver (top inset). While traction is held with this suture, the tenodesis driver is advanced to touch the tendon graft (bottom inset), and the entire tendon, driver, and screw complex is placed into the coracoid bone tunnel.

TECHNIQUES

- Tendon ends are bulleted for easy passage through bone tunnels.
- A whipstitch or grasping suture is placed in the two free ends of the tendon for graft passage through bone tunnels.
- The graft is ready for use if the surgeon is performing our preferred looping method. However, an alternative method is interference screw fixation to the coracoid process.
- In this option, the graft is folded with one short limb (about 3 inches) and a limb containing the remaining length of the tendon. A no. 2 ultra-high-strength nonabsorbable suture is placed through the doubled-over tendon graft in a Krakow manner (TECH FIG 2B).

Coracoid Preparation

- Standard looping technique
  - A graft can be looped around the base of the coracoid process using an aortic cross-clamp (Stanitsky clamp) or a suture-passing device (Arthrex, Inc., Naples, FL) for biologic fixation.
  - A heavy no. 2 ultra-strength nonabsorbable suture is also placed around the coracoid for use as a nonbiologic form fixation (TECH FIG 3A,B).
- Alternative technique: interference screw fixation to coracoid (TECH FIG 3C)
Although we currently do not use this method, some may choose to anchor the tendon into the base of the coracoid.

The diameter of the doubled-over portion of the graft is measured with a standard tendon-measuring device. Using this number, the appropriate cannulated reamer is chosen (6 or 7 mm).

The surgeon should use a smaller reamer diameter first and ream up in size if necessary.

Finger palpation of both lateral and medial portions of the coracoid process and drilling into the coracoid base under direct visualization with a cannulated reamer guide pin are completed.

One limb of the Krakow suture is passed through a 5.5 × 8-mm nonabsorbable radiolucent tenodesis screw and driver using a Nitinol wire.

The tenodesis driver is advanced to touch the tendon graft, and the entire tendon, driver, and screw complex is placed into the coracoid bone tunnel until 15 mm of the Krakow suture disappears.

The sutures from the graft are tied together over the existing interference screw, giving both interference screw and suture anchor advantages.

Clavicle Preparation

To recreate the conoid ligament, a cannulated guide pin is placed 45 mm away from the distal end of the clavicle and as posterior as possible, taking into consideration the space needed to not “blow out” the posterior cortical rim during reaming.

A 6-mm cannulated reamer is used to create the tunnel (TECH FIG 4).

If there is a question of what size reamer to use, starting with the smallest reamer necessary is always a good technique; if necessary the surgeon can ream up.

The surgeon reams in under power.

The surgeon disconnects the power driver and pulls the reamer out manually to ensure that the tunnel is a perfect circle and not widened by uneven reaming.

The same procedure is repeated for the trapezoid ligament, which is a more anterior structure than the conoid.

This tunnel is centered on the clavicle, approximately 15 mm lateral of the center portion of the previous tunnel.

Graft Fixation and Reconstruction

The limbs of the graft are crossed over the coracoid and one limb of the biologic graft is placed through the posterior bone tunnel, recreating the conoid ligament.

The other limb is passed through the anterior bone tunnel in the same fashion, recreating the trapezoid ligament (TECH FIG 5).

The no. 2 ultra-high-strength nonabsorbable suture placed around the coracoid is also passed through the tunnels for nonbiologic augmentation of the repair.

Upper displacement of the scapulohumeral complex and the use of a large point-of-reduction forceps placed on the coracoid process and the clavicle by the assistant are used to reduce the AC joint.

Fluoroscopy is used to confirm proper placement of the grafts and reduction of the AC joint.

The graft is pulled on cyclically multiple times and passed through the tunnels back and forth to reduce any displacement that might occur after fixation.

This step is critical to ensure that there is no migration or movement after the fixation is complete.

Nevertheless, we often overreduce the AC joint by 2 to 3 mm with the knowledge that a few millimeters of displacement still occurs.

The graft is positioned so that the graft tail representing the conoid ligament is left 2 cm proud from the superior margin of the clavicle. The long tail of the graft exits the trapezoid tunnel and will later be used to augment the AC joint repair if indicated (see Tech Fig 5).

With traction placed on the graft, ensuring its tautness, a 5.5 × 8-mm nonabsorbable radiolucent screw is placed in the posteromedial tunnel anterior to the conoid ligament graft.

Again, the graft is cyclically loaded multiple times. While holding reduction and tension on the ligament, another 5.5 × 8-mm nonabsorbable radiolucent screw is placed in the lateral trapezoid tunnel anterior to the trapezoid ligament graft.

With both grafts secured, the no. 2 ultra-high-strength nonabsorbable suture is tied over the top of the clavicle, becoming the nonbiologic fixation for the reduced AC joint.

TECH FIG 4 • A. Anatomic reconstruction of the coracoclavicular ligaments. For conoid ligament reconstruction, a guide pin is placed in the clavicle 45 mm from the acromioclavicular joint in a posteromedial position. For trapezoid ligament reconstruction, a guide pin is placed 30 mm from the acromioclavicular joint centered on the clavicle. B. After confirming the positions of the pins, a 5.5-mm cannulated drill is used to drill the clavicle. Care should be taken to place the conoid tunnel as far posterior as possible without violating the posterior cortex during reaming.
For acute injuries, we perform an AC joint repair. The AC joint is exposed. Simple or figure 8 sutures using a no. 0 nonabsorbable suture are used to repair the AC joint capsule and ligaments primarily. The posterior and superior ligaments are key in preventing posterior displacement of the clavicle. The repair can be augmented by using the limbs of the graft used for the coracoclavicular ligament repair. The short limb of the graft exiting the medial tunnel is folded laterally and sewn to the base of the graft exiting the trapezoid tunnel in series (TECH FIG 6A). The long limb exiting the lateral (trapezoid) tunnel is taken laterally and looped on top of the AC joint and used for augmentation of the AC joint capsule repair (TECH FIG 6B,C).

In chronic dislocations, two options exist. One is to repair the AC joint as detailed above for acute AC joint injuries. Alternatively, if arthrosis is a concern, a distal clavicle excision can be performed. An oscillating osteotome is used to remove 1 cm of the distal clavicle. The posterior cortical rim is beveled. The deltoidtrapezial fascia is meticulously closed using interrupted nonabsorbable sutures, taking care to leave the knots on the posterior aspect of the trapezius.

A simple suture can be used to bury the knot if it is prominent. Making clear full-thickness flaps during the approach and using tagging sutures allows for secure coverage of the grafts and clavicle.

A. The short limb of the graft representing the conoid ligament is folded laterally and sewn to the graft base representing the trapezoid ligament. (continued)
The long limb representing the trapezoid ligament can be taken laterally and used to augment the acromioclavicular ligament fixation.

**Biologic Fixation: Coracoacromial Ligament Transfer**
- The CA ligament is dissected out, especially laterally.
- The CA ligament is detached from its footprint that extends posteriorly on the acromion (TECH FIG 8A).

**MODIFIED WEAVER-DUNN PROCEDURE**
- Diagnostic arthroscopy is done if concomitant injuries are suspected.
- An incision is made 1.5 cm from the AC joint starting at the posterior clavicle in a curvilinear fashion toward the coracoid along the lines of Langer.
  - The incision is sometimes angled because the key is to have full visualization of the AC joint laterally and coracoid process medially.
- Superficial skin bleeders are controlled down to the fascia of the deltoid with a needle-tip Bovie.
- Full-thickness flaps are made from the midline of the clavicle both posteriorly and anteriorly, skeletonizing the clavicle (TECH FIG 7).
- Alternatively, a “hockey stick” incision can be made laterally from the acromion along the midportion of the clavicle, ending in a hockey stick fashion down toward the coracoid.
  - Periosteal flaps are elevated and a tagging suture can be placed at the medialmost aspect of the flap for accurate closure.

- Two heavy nonabsorbable sutures are placed at the end of the ligament using a whipstitch.
- The CA ligament is held directly superiorly and the corresponding area is marked on the clavicle.
  - This marks the amount of clavicle that needs to be resected to allow easy passage of the CA ligament without sharp turns.
  - If adequate arthroscopic resection has not already been performed, an oscillating saw is used to make an oblique cut on the clavicle, leaving more bone superiorly rather than inferiorly, at the level of the previously marked site.
- An intramedullary pocket is curetted inside the clavicle for the CA.
- The AC intra-articular disc is resected, leaving the AC ligaments undisturbed.
- A 2.0-mm drill is used to make two drill holes in a cruciate fashion (lateral clavicle anteriorly, medial clavicle posteriorly) 20 mm medial to the distal cut end of the clavicle (TECH FIG 8B).
  - A wire-loop is used to pass each limb of the CA ligament suture through the end of the clavicle and out the drill hole made superiorly.
  - For augmentation of CA ligament transfer, a 3.5-mm drill hole is made into the clavicle medial to the previously made drill holes for the CA ligament.
TECH FIG 8 • A. The ligament is released from the acromion and sutures are placed in the end. B. After a distal clavicle resection, two 2-mm unicortical drill holes are placed in the posterosuperior surface of the distal clavicle, exiting through the intramedullary canal. (Adapted from Galatz LM, Williams GR Jr. Acromioclavicular joint injuries. In: Bucholz RW, Heckman JD, Court-Brown C, eds. Rockwood and Green’s Fractures in Adults, vol 2. Philadelphia: Lippincott Williams & Wilkins, 2006:1354.)

□ For nonbiologic augmentation, a suture cord is constructed.
□ The surgeon takes three no. 1 absorbable sutures clamped at both ends. One clamp is turned clockwise while holding the other end until the sutures are intertwined together for the entire length of the sutures.
□ This is done with two other sets of three sutures.
□ The three sets are intertwined counterclockwise in the same fashion, resulting in a cord of nine total sutures. The suture cord is passed around the coracoid and through the 3.5-mm drill hole in the clavicle.
□ For biologic augmentation an autograft or allograft can be used.

Reduction and Fixation
□ Upper displacement of the scapulohumeral complex and the use of a large point-of-reduction forceps placed on the coracoid process and the clavicle by the assistant are used to reduce the AC joint.
□ Slight overreduction during fixation is recommended.
□ After reduction is achieved, the surgeon pulls the suture limbs of the CA ligament reconstruction, exiting the bone tunnels, and ties them on the superior surface of the clavicle (TECH FIG 9).
□ The pocket for the CA ligament must be long enough so that after anatomic reduction, the graft is nice and taut.
□ If the suture cord was used, the suture cord that was passed around the coracoid and through the clavicle is tied.
□ The surgeon should attempt to place the knot in the least prominent area.
□ The ends of the suture cord are unraveled and each individual suture limb is tied to prevent unraveling of the cable.
□ Finally, all free suture ends are cut.
□ If ligament augmentation was used, the ligament is wrapped in a figure 8 fashion and sutured to itself using heavy nonabsorbable sutures.
□ Closure is the same as the ACCR technique (see Tech Fig 6C).

TECH FIG 9 • Using a curette, a pocket is made inside the clavicle for the coracoacromial (CA) ligament. The CA ligament is transferred to the intramedullary canal. The sutures are placed through the drill holes and tied over the top of the clavicle. This pocket has to be large enough so that after reduction of the joint, the CA ligament can be pulled inside without any impediment. If this is done correctly, the ligament should be taut and not overstuffed inside the pocket. (Adapted from Galatz LM, Williams GR Jr. Acromioclavicular joint injuries. In: Bucholz RW, Heckman JD, Court-Brown C, eds. Rockwood and Green’s Fractures in Adults, vol 2. Philadelphia: Lippincott Williams & Wilkins, 2006:1354.)
ARTHROSCOPIC STABILIZATION

- The patient is placed in a beach-chair position. Draping is similar to the open procedures, with wide exposure and the arm draped free.

Establishing Portals

- A standard posterior portal is made, followed by two anterior portals (TECH FIG 10).
  - An anterosuperior portal is made using an outside-in technique, using a spinal needle to confirm positioning.
  - Débridement of the rotator interval is done until the tip of the coracoid is visualized.
  - Release of the superior glenohumeral ligament and partial release of the middle glenohumeral ligament may be required for adequate exposure.
  - A 7-mm partially threaded cannula is used for the anterosuperior portal.
  - An anteroinferior portal is made near the tip of the coracoid, again with the outside-in technique, using a spinal needle to confirm positioning and ensuring that the base of the coracoid can be reached using this portal. An 8.25-mm twist-in cannula is inserted for this portal.
  - A 70-degree scope may improve visualization of the coracoid base.
  - If the 30-degree arthroscope is used, the arthroscope position is changed to the anterosuperior portal.
  - The coracoid base is exposed using mechanical shavers and radiofrequency devices.
  - Any bursa or periosteum is stripped to obtain a full view of the coracoid base.

Drilling

- The assembled “Adapteur Drill Guide C-Ring with the Coracoid Drill Stop and Graduated Guide Pin Sleeve” (Arthrex, Inc., Naples, FL) is inserted through the anteroinferior portal (TECH FIG 11A).
  - With the drill stop placed at the base of the coracoid (as close to the scapula as possible), the corresponding area is marked on the superior aspect of the clavicle for the guide pin sleeve.
  - This area should be centered on the clavicle and approximately 25 mm from the AC joint.
  - A 1.5-cm incision is made over the clavicle in the lines of Langer, and the surgeon dissects down through the deltopectoral fascia.
Under direct visualization using the arthroscope, the surgeon places a 2.4-mm guide pin through the drill tip guide, clavicle, and coracoid until the drill stop is engaged (TECH FIG 11B,C).
- It is important to place the guide pin centered in the base of the coracoid.
- A 4.0-mm cannulated drill is used to drill the clavicle and coracoid while the drill stop prevents migration of the guide pin. The surgeon should always use the arthroscope for direct visualization and avoid drilling beyond the coracoid base (TECH FIG 11D,E).

**Suture Passage and Tying**
- The power drill is detached, leaving the cannulated drill in place.
- An 18-inch Nitinol suture passing wire is passed down through the cannulated drill and the tip is grasped with the arthroscopic grasper (TECH FIG 12A,B).
  - The drill can now be removed.
- Using the Nitinol passing wire, the two white traction sutures of the oblong button of the TightRope System are passed through the clavicle and coracoid while the blue sutures are kept on the anteroinferior side of the clavicle. (TECH FIG 12C-F).

**TECH FIG 12**
- **A.** The power drill is detached and the cannulated drill is used as a portal to pass an 18-inch Nitinol suture passing wire. **B.** A grasper is used to hold the Nitinol suture while the drill bit is removed. The limb of the Nitinol passing wire is brought out of the anteroinferior portal, leaving the loop superior to the clavicle. **C.** The Nitinol suture passing wire is used to deliver the white traction sutures through the clavicle and coracoid and out of the anteroinferior portal. **D,E.** While holding the blue TightRope suture tails, pulling on one of the white suture tails flips the oblong button to a vertical position, allowing passage of the TightRope through the clavicle and coracoid. **F.** Once past, independent pulling on the white sutures flips the oblong button back to a horizontal position, anchoring it underneath the coracoid. (A,D: Courtesy of Arthrex, Inc.)

**TECH FIG 13**
- Placing the arthroscope into the subacromial space via the posterior portal helps to directly visualize the reduction. After reduction of the clavicle, sequential pulling on the blue TightRope suture tails delivers the round button down to the superior clavicle, holding the reduction firmly. The blue sutures are tied securely. (Courtesy of Arthrex, Inc.)
passed through the clavicle, the coracoid, and the anteroinferior portal (TECH FIG 12C).

- The blue TightRope suture tails of the round button are held firmly with one hand. The surgeon pulls on the white suture tails attached to the oblong button. This flips the oblong button to a vertical position and allows passage through the drill holes (TECH FIG 12D,E).
- The oblong button is pulled through the clavicle and coracoid.
- Once passed, differential pulling on the white sutures flips the button to a horizontal position, preventing it from retracting through the drill holes (TECH FIG 12F).

### Clavicle Reduction

- The surgeon pulls on the blue suture tails to advance the round button down to the clavicle. The sutures are tied over the top of the TightRope, making a surgeon’s knot and two reverse half-hitches.
- Leaving the tails long helps the knot to lie flat (TECH FIG 13).
- All wounds are irrigated and closed.

### Pearls and Pitfalls

<table>
<thead>
<tr>
<th>Positioning and approach</th>
</tr>
</thead>
<tbody>
<tr>
<td>The surgeon should make sure that the patient’s head can be repositioned to the side, allowing room for conoid tunnel drilling.</td>
</tr>
<tr>
<td>An alternative is to displace the clavicle anteriorly with a towel clip to allow access for conoid tunnel drilling.</td>
</tr>
<tr>
<td>The deltoid and trapezial fascia are tagged for good repair.</td>
</tr>
</tbody>
</table>

<table>
<thead>

### Postoperative Care

- Postoperative support with a Lerman Shoulder Orthosis (DJO Inc., Vista, CA) or a Gunslinger Shoulder Orthosis (Hanger Prosthetics & Orthotics, Inc., Bethesda, MD) is used for 6 to 8 weeks. These braces are recommended to counter the pull on the shoulder complex by gravity.
- For the first 6 to 8 weeks, the brace may be removed for grooming and supine gentle passive range of motion only.
- Active and passive range-of-motion exercises are started at 8 weeks after surgery.
- If painless range of motion is obtained, strength training is started at 12 weeks.

### Outcomes

- Anatomic coracoclavicular reconstruction: unpublished data from an ongoing study (level IV evidence) at our institution between 2002 and 2006;
  - 427 cases of AC joint dislocations with a surgical rate of 3.7%
  - 16 cases (two revisions)
  - Mean postoperative months: 28.9
  - One failure (noncompliant)
  - To date, preliminary results show a mean Single Assessment Numeric Evaluation (SANE) score of 98.4/100.

Other outcome measures, including American Shoulder and Elbow Surgeons (ASES), Rowe, and Constant scores, are 94.1, 91, and 96, respectively. Patients have a pain rating of less than 1/10 with horizontal adduction and forward elevation and when a posterior force is directed at the AC joint. Postoperative radiographs show that the mean difference in the coracoclavicular distance is 2.1 mm compared to the contralateral side.

- **Weaver-Dunn**
  - Outcomes are difficult to compare due to the variations in the Weaver-Dunn method used and the makeup of the type of patients and severity of injury within study groups.
  - Rauschning et al reported 12 acute and 5 chronic type III AC joint injuries treated by the Weaver-Dunn procedure. At follow-up 1 to 5 years after the operation, all patients had stable and painless shoulders with resumption of full activities and functionally excellent results (level IV evidence).
  - Tienen et al presented 21 patients with Rockwood type V AC joint dislocations who underwent a modified Weaver-Dunn procedure with clavicle reduction and AC joint fixation using absorbable braided sutures. At a mean follow-up of 35.7 months, 18 patients had returned to their sports without pain within 2.5 months after operation; the average Constant score at last follow-up was 97. Radiographs taken at this time showed residual subluxation in two patients.
and, in one patient, redislocation of the joint that occurred because of infection (level IV evidence).

- When chronic and acute repairs of type III AC joint injuries were studied, patients with early repair were significantly better after 3 months. In a study by Weinstein et al., 26 of 27 (96%) patients with early repairs and 13 of 17 (77%) patients with late reconstructions achieved satisfactory results with an average 4-year follow-up (level IV evidence).

- Arthroscopic reconstruction with the TightRope System: preliminary results of an ongoing study:
  - 29 patients with a mean age of 31 years and 6-month follow-up
  - Mean Constant score 91.1
  - Mean ASES score 96.6
  - Return to sports mean of 12 weeks
  - Complications: one hardware failure with revision using TightRope and one patient with transient adhesive capsulitis

COMPlications

- Loss of reduction
- Excessive distal clavicle resection
- Osteolysis due to nonbiologic fixation material
- Coracoid fracture
- Infection

REFERENCES

DEFINITION
- Acromioclavicular (AC) separations are relatively rare injuries that result in disruption of the AC complex.
- Overall incidence of the injury is 3 to 4 per 100,000 in the general population, with up to 52% of cases occurring during sporting events.\(^5\)
- The degree of injury is based on the amount of force transmitted through the acromion to the distal clavicle and the surrounding deltotrapezial fascia.\(^1,12,19\)
- Increased force transmission leads to dissociation of the AC joint and tearing of the coracoclavicular ligaments.
- Determination of the injury type will guide operative versus nonoperative management.\(^12\)

ANATOMY
- The AC joint is a diarthrodial joint composed of the medial acromial margin and the distal clavicle.
- A fibrocartilaginous intra-articular disc between the two bony ends decreases contact stresses.\(^12\)
- Dynamic stability of the AC joint is provided by the trapezial fascia and the overlying anterior deltoid.
- Static stability of the AC joint is provided by:
  - AC ligaments
    - The superior ligament provides the greatest restraint to anterior translation of the distal clavicle.
    - Anterior, posterior, and inferior ligaments add additional horizontal stability to the AC joint.
  - Coracoclavicular ligaments
    - Conoid: arises from the posteromedial aspect of the coracoid and inserts on the posterosmedial clavicle
      - Measures about 2.5 cm long and 1 cm wide
      - Provides primary resistance against anterior and superior loading of the clavicle
    - Trapezoïd: arises from the anterolateral coracoid just posterior to the pectoralis minor and attaches to the lateral or central clavicle
      - Measures about 2.5 cm long and 2.5 cm wide
      - Provides resistance against posterior loading of the clavicle

PATHOGENESIS
- AC separations are the result of a direct force to the lateral aspect of the shoulder with the arm adducted (ie, fall on point of the shoulder).
- The degree of injury to the AC joint, deltopectoral fascia, and coracoclavicular ligaments will determine the resultant deformity.
- Most low-grade injuries involve only the AC joint and are often self-limited.
- Severe arm abduction during the AC separation can result in subacromial or subcoracoid displacement of the distal clavicle.\(^12\)

PATIENT HISTORY AND PHYSICAL FINDINGS
- A complete physical examination of both upper extremities with the patient appropriately attired and in the upright position is standard.
- Evaluation of the neck and a complete neurologic examination are essential, as higher-grade injuries may manifest with brachial plexus compromise.
- Low-grade injuries will be tender to palpation at the AC joint, with mild elevation possible. Increased deformity is commonly seen as the injury grade increases, but acutely the deformity may be masked by swelling.
- Methods for examining the AC joint include:
  - AC joint compression (shear) test: Isolated painful movement at the AC joint in conjunction with a history of direct trauma indicates AC joint pathology.
  - Cross-arm adduction test: Look for pain specifically at the AC joint. Pain at the posterior aspect of the shoulder or the lateral shoulder might indicate other pathology.
  - Paxino test: sometimes done in conjunction with bone scans to assess damage to AC joint
  - O’Brien test: Symptoms at the top of the joint must be confirmed by the examiner palpating the AC joint. Anterior glenohumeral joint pain suggests labral or biceps pathology.
  - Local point tenderness at the AC joint while the glenohumeral joint is kept still suggests localized AC joint pathology.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard shoulder radiographs can be useful for diagnosis, but overpenetration may result in poor visualization of the AC joint.
- An axillary view should be included to avoid missing a glenohumeral dislocation and to help assess anteroposterior (AP) translation of the clavicle.
A 10- to 15-degree cephalic tilt view (Zanca) avoids superposition of the scapular spine and improves visualization of the AC joint. This also allows evaluation for loose bodies or small fractures that may be missed with standard views of the shoulder (FIG 1).12

- Sling for comfort, range-of-motion exercises, and avoidance of contact sports for 6 to 8 weeks may suffice.
- Padding of the residual deformity for contact athletes may be beneficial. Additional trauma may lead to the development of a higher-grade injury.
- Types IV and VI are routinely treated operatively.

**SURGICAL MANAGEMENT**

- Indication for surgery is an acute Rockwood type III or VI injury in an active patient unwilling to accept the cosmetic deformity and dysfunction of the affected shoulder.
- The TightRope fixation system (Arthrex, Naples, FL) was originally designed for the treatment of syndesmotic injuries. It has two metal fixation buttons with a continuous loop of no. 5 FiberWire running between them.17
- The technique allows for a quick and relatively simple arthroscopic fixation of acute, high-grade AC separations. Chronic injuries should have the coracoclavicular ligaments reconstructed with autologous or allograft tissue.

**DIFFERENTIAL DIAGNOSIS**

- Distal clavicle fracture
- Acromial fracture
- Glenohumeral dislocation
- Sternoclavicular dislocation
- Scapulothoracic dissociation

**CLASSIFICATION**

- Rockwood (modification of Allman, Tossey, and Bannister’s work) described six types of injuries to the acromioclavicular joint (Table 1).1,2,12,29

**NONOPERATIVE MANAGEMENT**

- Types I and II
  - Most authors agree that nonoperative management is the treatment of choice for these incomplete injuries.1,12,16,20
  - A simple sling for comfort is used, with progression to range of motion as tolerated in 1 to 2 weeks.
  - Return to sports is authorized when the patient has pain-free range of motion and normal strength.
- Type III
  - This is more controversial, although conservative treatment is often successful.

- Sling for comfort, range-of-motion exercises, and avoidance of contact sports for 6 to 8 weeks may suffice.
- Padding of the residual deformity for contact athletes may be beneficial. Additional trauma may lead to the development of a higher-grade injury.
- Types IV and VI are routinely treated operatively.

- Stress radiographs
  - Standing views with 10 to 15 pounds of traction applied to the wrists are recommended by some authors to help distinguish the grade of injury because patients may guard with standard standing views.
  - Recent literature does not support the routine use of stress radiographs.21 They do not affect the decision-making process for operative versus nonoperative management.12,21 However, one AP view with both AC joints visible is helpful to account for normal variants and determine the degree of displacement.

**CLASSIFICATION**

- Rockwood (modification of Allman, Tossey, and Bannister’s work) described six types of injuries to the acromioclavicular joint (Table 1).1,2,12,29
- This classification scheme has proven to be effective for prognosis and treatment.

**NONOPERATIVE MANAGEMENT**

- Types I and II
  - Most authors agree that nonoperative management is the treatment of choice for these incomplete injuries.1,12,16,20
  - A simple sling for comfort is used, with progression to range of motion as tolerated in 1 to 2 weeks.
  - Return to sports is authorized when the patient has pain-free range of motion and normal strength.
- Type III
  - This is more controversial, although conservative treatment is often successful.
ESTABLISHING ANATOMY AND PORTALS

- Anatomy is identified: coracoid, acromion, clavicle (length and width), AC joint.
- Portals are marked: posterior, anterior inferior, and anterolateral.
- The posterior portal is created for viewing 2 cm inferior and 2 cm medial to the posterolateral edge of the acromion in the “soft spot.”
  - Diagnostic arthroscopy with a 30-degree scope of the intra-articular space is routine.20
- The subacromial space is entered from this portal using standard technique.
- We do not find it necessary to move through the rotator interval to identify the coracoid base, although it is recommended in the technique guide.
- A 70-degree scope may be helpful if the trans-interval technique is used.
- The anterolateral portal is made using an “outside-in technique” in line with the lateral edge of the acromion and the coracoid as a working portal.
- A 5- to 7-mm cannula is introduced to assist with pressure control.

CORACOACROMIAL LIGAMENT AND CORACOID PREPARATION

- With the scope in the posterior portal, the anterolateral acromion and the coracoacromial (CA) ligament are identified. The CA ligament is preserved (TECH FIG 1A).
- The CA ligament is followed to its attachment site on the coracoid (TECH FIG 1B).
- Through the anterolateral portal an arthroscopic ablator or chondrotome is used to resect the subcoracoid bursa and allow better visualization of the inferior aspect of the coracoid and its base.
- There is no need to remove soft tissue from the superior aspect of the coracoid (TECH FIG 1C).
- The surgeon should be cautious when placing instruments medial to the coracoid because the scapular notch lies in close proximity. Injury to the neurovascular bundle is a possibility.
- An 18-gauge spinal needle is used for localization and an “outside-in technique” is used to make the anteroinferior portal just lateral and slightly inferior to the coracoid. An 8.25-mm cannula is inserted.
- The Adapter Drill Guide C-Ring and Coracoid Drill Stop (Arthrex) is inserted through the anteroinferior portal under the base of the coracoid (TECH FIG 1D).
- The surgeon should stay as far posterior, near the coracoid base, as possible, and central from a mediolateral standpoint.
- A 1- to 2-cm incision is made over the clavicle in line with the drill guide and the coracoid.

TECH FIG 1 • A. Coracoacromial ligament identification. B. Coracoid identification. C. Soft tissue resection of the coracoid. D. Coracoid drill stop placement. The base is hugged posterior.
GUIDE PIN PASSAGE

- Under arthroscopic visualization with the clavicle reduced, a 2.4-mm guide pin is advanced through the center of the clavicle and coracoid. It is captured by the drill stop (TECH FIG 2A).
- The guide pin is overreamed with a 4-mm cannulated reamer, using the drill stop to prevent plunging. The scope allows visualization of each step (TECH FIG 2B).
- The guide pin is removed and the solid end of the Nitinol wire loop is passed antegrade through the cannulated reamer. It is grasped and removed out the anteroinferior portal with a push-and-pull technique (TECH FIG 2C,D).

SUTURE PASSAGE

- The TightRope comes fixed with two 2-0 FiberWires to lead the suture button through the bone tunnel and flip accordingly.
- These are passed with the wire loop through the clavicle and coracoid and out the anteroinferior portal.
- One suture strand should be colored purple with a marking pen for easier differentiation of the “lead” suture from the “flip” suture (TECH FIG 3A,B).
- The TightRope button is passed and flipped when visualized with the arthroscope (TECH FIG 3C,D).
- The upper extremity is then elevated and the AC joint is overreduced.

TECH FIG 2 • A. Captured 2.4-mm guide pin. B. Captured 4-mm drill bit. C. Nitinol wire passage. D. Retrieval of Nitinol through the anteroinferior portal.

TECH FIG 3 • A. Colored “lead” suture. B. Suture button exits coracoid base. (continued)
POSTOPERATIVE CARE
- A sling is used for comfort and to slow down the patient for 4 weeks.
- Range of motion of the elbow is permitted immediately, as are gentle Codman/pendulum exercises.
- Gentle active motion below the shoulder level is permitted until the 6-week mark, at which time progression to full motion is authorized.
- No heavy work or athletics are permitted for 3 months.
- Postoperative radiographs are compared with radiographs made at the 6-week return visit.

COMPLICATIONS
- Infection
- Loss of reduction
- Coracoid fracture
- Clavicle fracture
- Suprascapular neurovascular bundle injury

OUTCOMES
- The TightRope Fixation System is a relatively new system for treatment of acute AC separations. It is not intended for chronic injuries.
- No long-term studies or prospective randomized trials are available.
- Biomechanical data are available only for its syndesmotic use.\(^{18,19}\)

ACKNOWLEDGMENTS
We thank John Morton, James Willobee, and Jeff Wyman from Arthrex, and the staff of the William Beaumont Army Medical Center Biomedical Research facility.

REFERENCES

DEFINITION

- Suprascapular nerve entrapment may result from constriction within the suprascapular notch, pressure from a ganglion cyst in the floor of the supraspinatus fossa, or a constriction at the spinoglenoid notch.
- The nerve is readily accessible via arthroscopic techniques developed by Thomas Samson and Laurent Lafosse.

ANATOMY

- The suprascapular nerve receives contributions primarily from the C5 root, with additional minor contributions from C4 and C6 nerve roots.
- It exits from the upper trunk of the brachial plexus through the supraclavicular fossa and comes through the suprascapular notch beneath the transverse scapular ligament, dividing into two branches.
- One branch exits medially to the supraspinatus muscle.
- The second continues across the floor of the supraspinatus fossa of the scapula toward the junction of the scapular spine and the posterosuperior neck of the glenoid.
- The nerve makes a short turn around the bone junction under the inconsistently present spinoglenoid ligament and travels medially across the superior aspect of the infraspinatus fossa of the scapula, sending branches into this muscle until terminating into the medial aspect of this muscle.

PATHOGENESIS

- Nerve entrapment usually occurs at the suprascapular notch.
- Trauma, repetitive overhead use requiring hyperretraction and protraction of the scapula (ie, volleyball), and chronic rotator cuff injuries may produce swelling in this area, resulting in pressure on the nerve.
- Congenital V-shaped suprascapular notch orientation has been implicated as a cause of this entrapment.
- Less common areas of entrapment may occur owing to ganglion cyst compression in the middle or posterior aspect of the fossa, and at the spinoglenoid notch.
- A thickened spinoglenoid ligament may cause entrapment at the spinoglenoid notch as well.
- Unusual sources of nerve entrapment include vascular expansion (aneurysm or varices) and tumors.

NATURAL HISTORY

- The natural history of suprascapular nerve entrapment depends on the cause and pathologic changes in the anatomy.
- Spontaneous recovery after rehabilitation treatment has been reported.
- However, if electromyographic nerve conduction studies show evidence of compression, surgical treatment is usually indicated.
- Compression at the suprascapular notch or spinoglenoid area is often the primary problem and is not associated with intra-articular pathology. Compression by ganglion cyst in the supraspinatus fossa is often associated with labral tears that require fixation along with débridement of the cyst. All of these may be managed arthroscopically if nonoperative treatment is ineffective.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient often presents with signs and symptoms of impingement and rotator cuff tearing, overhead weakness, pain on forced flexion, and subacromial crepituation.
- Careful inspection may reveal atrophy in the supraspinatus and infraspinatus fossa compared to the opposite side.
- Weakness to supraspinatus isolation, infraspinatus isolation, and Whipple testing is usually present.
- Palpation of the rotator cuff reveals no defect. However, there is usually no, or only minimal, palpable swelling on the distal supraspinatus tendon.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Most patients will have to undergo magnetic resonance imaging.
- The test should reveal an intact rotator cuff with atrophy of the supraspinatus and infraspinatus musculature.
- Occasionally, there will be tearing of the rotator cuff with atrophy that is not in proportion to the size or duration of the tear.
- Electromyographic nerve conduction studies by a neurologist specializing in proximal entrapment lesions of the upper extremity will be definitive in cases of entrapment at the suprascapular or spinoglenoid notch.

DIFFERENTIAL DIAGNOSIS

- The main confusion in this area is with primary impingement and rotator cuff tears.
- The history and physical examination are often similar, but a careful evaluation and physical examination will reveal the differences as delineated in the prior discussion under physical findings.

NONOPERATIVE MANAGEMENT

- There is a limited role for nonoperative treatment of true entrapment neuropathy.
- Pressure from a cyst may be alleviated by aspiration of the cyst.
- Compression at either the suprascapular or spinoglenoid notch, however, will require release if the nerve conduction study reveals pressure to the nerve in these areas.

SURGICAL MANAGEMENT

- Several approaches to open release have been described (Nicholson, Vastamake, and Post).
- Recently, Samson and Lafosse have each focused interest on techniques of arthroscopic release.

Positioning

- The patient is positioned in the lateral decubitus (preferred) or beach-chair position.
A diagnostic glenohumeral arthroscopy is performed to rule out intra-articular pathology. The arthroscope is then positioned in the lateral portal of the subacromial bursa in line with the anterior acromion, providing a picture of the supraspinatus muscle and tendon (TECH FIG 1A). It is advanced along the anterior edge of the supraspinatus until the base of the coracoid is visualized (TECH FIG 1B).

A switching stick is placed in the lateral Neviaser portal and used to palpate along the anterior edge of the supraspinatus fossa medial to the medial aspect of the base of the coracoid (TECH FIG 1C).

A full-radius shaver can be used from the anterior portal to remove soft tissue as long as it remains lateral to the switching stick, which is functioning as a retractor in addition to a diagnostic tool (TECH FIG 1D).

On encountering the suprascapular artery, a second medial Neviaser portal is created and the retracting switching stick is removed to this portal and used to pull the artery medially and protect it (TECH FIG 1E).

Sliding this retractor along the top of the ligament will also protect any aberrant branches of the nerve that pass superior to the ligament.

**TECH FIG 1**

A. When positioning the arthroscope in the lateral portal of the subacromial bursa in line with the anterior acromion, the supraspinatus muscle and tendon can be seen. B. Advancing the arthroscope along the anterior edge of supraspinatus allows the surgeon to visualize the coracoid. C. Placing a switching stick in the lateral Neviaser portal allows the surgeon to palpate the anterior edge of the supraspinatus fossa medial to the medial aspect of the base of the coracoid. D. A shaver can be used from the anterior portal to remove soft tissue; the surgeon must always remain lateral to the switching stick. E. A second Neviaser portal is established so that the switching stick can be used to pull the artery medially and protect it. F. A blunt probe enters to identify the ligament and protect the underlying nerve. G,H. A side biter or shaver can be used to release the ligament. I. The exposed nerve. J. The suprascapular nerve, artery, and vein are allowed to fall back into a relaxed position.
The primary complication would be inadvertent nerve resection, but this has not been reported to our knowledge.

**REFERENCES**

DEFINITION
- Shoulder stiffness can be a function of soft tissue scarring and contracture or osseous changes.
- The stiff or frozen shoulder has been given the name adhesive capsulitis.
- There are principally two forms of adhesive capsulitis that result in loss of range of motion and can be safely addressed by arthroscopic releases:
  - Primary adhesive capsulitis (idiopathic)
  - Secondary adhesive capsulitis
    - Associated with metabolic disorder (diabetes mellitus, thyroid disorder)
    - Posttraumatic
    - Postoperative
- Shoulder stiffness can result from intra-articular adhesions, capsular contracture, subacromial adhesions, and subdeltoid adhesions.
- The essential tenet of treating the stiff shoulder is recognizing the anatomic region responsible for the stiffness and releasing the specific structures in this region in a controlled fashion.
- An adequate appreciation of anatomy is key to restoring motion and avoiding injury to accompanying tendons and nerves.

ANATOMY
- Shoulder motion occurs principally along two interfaces:
  - Glenohumeral articulation
  - Scapulothoracic articulation
- On average, the normal ratio of glenohumeral motion to scapulothoracic motion is 2:1, with the majority of elevation occurring through the glenohumeral joint.
- Capsuloligamentous structures contribute to stability of the shoulder joint and act as check reins at the extremes of motion in their nonpathologic condition.
- Many areas within the capsule are thickened and contain the glenohumeral ligaments (FIG 1A):
  - Superior glenohumeral ligament
  - Coracohumeral ligament
  - Middle glenohumeral ligament
  - Inferior glenohumeral ligament complex
    - Anterior band
    - Axillary fold
    - Posterior band
- The rotator interval is a triangular region between the anterior border of the supraspinatus tendon and the superior border of the subscapularis. It contains the superior glenohumeral ligament and the coracohumeral ligament.
- During shoulder motion, tightening and loosening of the glenohumeral ligaments and capsule are accompanied by lengthening and shortening of the rotator cuff and deltoid muscles.
  - A plane between the deltoid and humerus (subdeltoid) exists that, when scarred, can limit glenohumeral motion.
  - A plane between the rotator cuff and acromion exists and is occupied normally by a subacromial bursa.
  - Scar tissue and adhesions in this interface can limit excursion of the rotator cuff and thus glenohumeral joint motion (FIG 1B).
- Several structures that are important to preserve are in continuity or proximity to the regions of the capsule that are released arthroscopically in the stiff shoulder.
  - The subscapularis tendon is superficial to the middle glenohumeral ligament. The superior two thirds of the subscapularis is intra-articular.

FIG 1 • A. Thickenings of the capsule are referred to as the glenohumeral ligaments. In their undiseased state they act as physiologic check reins at extreme ranges of motion. B. Fibrous bands can exist in the subacromial space (a) between the acromion and rotator cuff as well as in the subdeltoid space (b) between the deltoid and rotator cuff or humerus. These can restrict excursion of the rotator cuff and thus active and passive range of motion. C. The axillary nerve runs across the superficial surface of the subscapularis and then adjacent to the inferior border of the subscapularis as it heads posteriorly. Anterior capsular release can proceed safely as long as the muscle of the subscapularis is seen inferiorly.
The biceps tendon courses through the rotator interval.
- The axillary nerve runs adjacent to the inferior border of the subscapularis and then is juxtaposed to the inferior glenohumeral ligament and capsule as it exits the quadrangular space (FIG 1C).
- The posterior capsule overlies a distinct layer of rotator cuff muscle posteriorly adjacent to the glenoid.
- The posterior rotator cuff tendons and capsule are juxtaposed and virtually indistinguishable more laterally.
- Release of the posterior capsule should be done adjacent to the glenoid to avoid rotator cuff muscle and tendon disruption.
- Contracture of specific capsular regions and ligaments correlates with specific clinical losses of range of motion. This must be determined preoperatively to guide arthroscopic release.
- These anatomic regions and their influence on shoulder motion are as follows:
  - Rotator interval (superior glenohumeral ligament and coracohumeral ligament) restricts external rotation with the shoulder adducted.
  - Middle glenohumeral ligament restricts external rotation at the midranges of abduction.
  - Inferior glenohumeral ligament (anterior band) restricts external rotation at 90 degrees of abduction.
  - Inferior capsule restricts abduction and forward flexion.
  - Posterior capsule and posterior band of the inferior glenohumeral ligament restrict internal rotation.

PATHOGENESIS
- Shoulder stiffness can be primary or secondary.
  - Secondary stiffness occurs as a result of scar formation and adhesions after trauma or surgery of the shoulder as a result of disruption of soft tissue, release of cytokines, and the body’s inflammatory response seen after injury.
  - Secondary stiffness can also result iatrogenically, as would be the case after a Putti-Platt or Magnuson-Stack procedure.
- Primary stiffness is often termed adhesive capsulitis.
  - Adhesive capsulitis, also referred to as frozen shoulder, can be idiopathic or associated with a secondary cause that is either intrinsic (eg, rotator cuff tears, biceps tendinitis, or calcific tendinitis) or extrinsic (eg, diabetes, myocardial infarction, knee disorders).
- There is no consensus on the definition of frozen shoulder, but it is generally agreed to be a condition with both significant restriction in active and passive range of shoulder motion without an osseous basis for this limitation.
- The pathogenesis of frozen shoulder has been divided into three stages (Table 1). The stages coexist as a continuum and occur over a variable time course in individual patients.

Table 1 Pathogenesis of Frozen Shoulder

<td>4 to 9 months or more</td>
</tr>
<tr>
<td>Thawing stage</td>
<td>Shoulder motion gradually returns to normal</td>
<td>5 to 26 months</td>
</tr>
</tbody>
</table>

NATURAL HISTORY
- Although the natural history of secondary shoulder stiffness is relatively accepted as protracted and refractory to nonoperative treatment, the time course and end result of adhesive capsulitis (primary and secondary) are more controversial.
- In the absence of operative intervention, recent reports have shown measurable restrictions in range of motion at follow-up in 39% to 76%\(^{3,8,10}\) of patients, in addition to persistent symptoms in up to 50%\(^{2}\) of patients with adhesive capsulitis.
- Adhesive capsulitis can be protracted, with the mean duration of symptoms 30 months.\(^{10}\)
- There is a weak correlation between restricted range of motion and pain.
  - Some patients have severe pain but near-normal range of motion.
  - Some patients have very restricted range of motion but no pain.
  - In one study, restricted range of motion was found in more than 50% of patients with adhesive capsulitis, but functional deficiency was identified in only 7% of the patients.\(^ {10}\)
- The impact of restricted range of motion or pain on an individual patient’s quality of life largely depends on that patient’s functional demands.
- Adhesive capsulitis in diabetics tends to be more protracted and more resistant to nonoperative treatment than idiopathic adhesive capsulitis.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with idiopathic adhesive capsulitis often deny a traumatic event but complain of the insidious onset of pain that is refractory to physical therapy and predates the loss of motion.
- Patients with secondary adhesive capsulitis often have a history of trauma, surgery, or medical comorbidities.
  - A history of fracture or extended immobilization should be elicited.
  - Previous surgeries including rotator cuff repair, capsular shift, Putti-Platt, Bristow-Latarjet, open glenoid bone grafting, and open reduction and internal fixation of a fracture should be documented as a potential cause of stiffness.
  - Comorbidities, including diabetes mellitus and thyroid disorders, should be recorded because they are associated with adhesive capsulitis.
- Symptoms expressed by patients with shoulder stiffness include:
  - Loss of range of motion that translates into functional limitations
  - Painful arc of motion
  - Pain often radiating to the deltoid area due to “non-outlet” impingement\(^{5}\)
Periscapular pain as a result of transferred pain to the scapulothoracic articulation because of restricted gleno-humeral range of motion

Acromioclavicular joint pain due to increased scapulothoracic motion

A comprehensive examination of the involved shoulder must be done to note any concomitant pathology. Physical examination methods include:

- Passive range-of-motion examinations
  - Assessing the anterosuperior capsule: Results are compared to the contralateral shoulder. A loss of passive range of motion in this position suggests contracture of the anterosuperior capsule in the region of the rotator interval. Loss of passive range of motion should always be compared to loss of active range of motion.
  - Assessing the anteroinferior capsule: A loss of passive external rotation in abduction suggests contracture of the anteroinferior capsule.
  - Assessing the inferior capsule: A loss of passive flexion and abduction suggests contracture of the inferior capsule.
  - Assessing the posterior capsule: Cross-chest adduction can be measured in degrees by recording the angle between an imaginary horizontal to the ground and the axis of the arm. A loss of passive internal rotation suggests contracture of the posterior capsule.
  - Lidocaine injection test: Passive and active range of motion in all planes should be recorded before injection. Once pain is alleviated, the postinjection increase in passive and active range of motion is recorded. The recorded increase in range of motion after the injection indicates the extent to which loss of motion is attributable to adhesions and soft tissue contracture as opposed to pain from non-outlet impingement or a symptomatic acromioclavicular joint.
  - Intra-articular injection: Passive and active range of motion should be recorded in all planes before injection. Passive and active range of motion should be evaluated after the injection to note any improvement after pain relief. A more accurate assessment of range of motion can be made after pain is alleviated. The injection can also be therapeutic in the early stages of adhesive capsulitis when synovitis is present.

- The shoulder should be examined for signs of previous surgery, trauma, deformity, and atrophy.
- Manual motor testing of rotator cuff and deltoid muscles should be done.
- Active and passive range of motion should be noted in all planes both in seated and supine positions. Shoulder motion should be viewed from the front and back of the patient.
  - Assessing range of motion in a supine position controls compensatory scapulothoracic motion and lumbar tilt, yielding a more accurate examination.
  - An equal loss of passive and active range of motion suggests adhesive capsulitis as the cause.
  - Greater loss of active than passive range of motion suggests rotator cuff or nerve injury.
  - Global loss of passive range of motion is typical of adhesive capsulitis, whereas loss of range of motion in one plane is usually attributable to postsurgical scarring or trauma.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Routine radiographic evaluation should include an anteroposterior (AP) view of the shoulder in neutral, internal, and external rotation, as well as scapular-Y and axillary lateral views.
  - Disuse osteopenia is often noted.
  - Concomitant findings may include osteoarthrosis, calcific tendinitis, or hardware signifying a previous surgical procedure (eg, open reduction and internal fixation, Putti-Platt) (FIG 2).
  - Magnetic resonance imaging (MRI) is obtained only if a rotator cuff tear or other soft tissue derangement is suspected.
  - We do not typically order an arthrogram or laboratory studies to confirm the diagnosis of adhesive capsulitis.

**DIFFERENTIAL DIAGNOSIS**

- Glenohumeral arthritis
- Acromioclavicular arthritis
- Rotator cuff tendinitis
- Subacromial or subdeltoid bursitis
- Bicipital tendinitis
- Calcific tendinitis
- Septic arthritis
- Rotator cuff tears
- Gout or crystalline arthropathy

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment can be attempted but is typically unsuccessful in patients with secondary shoulder stiffness.
  - It is indicated in patients with primary and secondary adhesive capsulitis who have had stiffness for less than 4 to 6 months or no previous treatment.
  - Nonsteroidal anti-inflammatories are used for pain relief but narcotics are avoided because of dependency issues with long-term use.

**FIG 2** • Hardware on radiographs can be helpful in guiding treatment. In this instance, after treatment of a proximal humerus fracture with a blade plate, adhesions would be expected in the subdeltoid space.
■ Injections are helpful in the early stages of adhesive capsulitis to control pain.
  ■ A series of three intra-articular injections can be given for pain relief. An intra-articular injection is often diagnostic as well, with the alleviation of pain but continued restriction in range of motion.7-9
  ■ Paired injections can be given (a subacromial and intra-articular injection).11
  ■ Active-assisted range-of-motion exercises focused on stretching capsular contractures under the supervision of a physical therapist should be done in 5- to 10-minute sessions four or five times a day.6 Other modalities such as ice and heat can provide comfort before and after exercise but are typically not very effective in the inflammatory or freezing phase.

SURGICAL MANAGEMENT
■ Surgical intervention should not be attempted during the early stages of adhesive capsulitis. It may be counterproductive and prohibit an increase in range of motion by abundant scar formation.
■ Surgical intervention is indicated for secondary or primary adhesive capsulitis once pain is present only at the extremes of motion and not through the entire arc of motion.
■ We prefer to continue nonoperative management while motion is increasing. We recommend surgery only when patients plateau.

We prefer to do a manipulation under anesthesia at the conclusion of an arthroscopic release in a controlled fashion rather than as a stand-alone procedure or before an arthroscopic evaluation and release.

Preoperative Planning
■ Imaging is reviewed and concomitant pathology is noted.
  ■ Rotator cuff tears should be noted because a repair will influence postoperative therapy and the timing of surgery.
  ■ Glenohumeral arthritis should be noted. These patients may have some benefit from an arthroscopic release, but their results are influenced by the congruity of the glenohumeral joint.
  ■ Unless contraindicated, we use regional anesthesia (30- to 40-cc bolus of a combination of 1.5% mepivacaine and 0.5% bupivacaine) with an indwelling interscalene catheter that provides muscle paralysis and pain control during the procedure as well as up to 48 hours after arthroscopic capsular release (FIG 3A).
  ■ This is essential to postoperative therapy and was shown to be effective and safe.4,13,14 Patients are admitted for 48 hours of intensive physical therapy under the indwelling interscalene block after surgery.
  ■ An examination under anesthesia is conducted using the range-of-motion principles to assess the anterosuperior, anteroinferior, inferior, and posterior capsules. This guides the emphasis of capsular release (FIG 3B).

Positioning
■ The patient is placed supine on the operating table in the beach-chair position.
■ After an examination under anesthesia, the shoulder is widely prepared and draped well medial to the coracoid anteriorly and to the medial scapular border posteriorly.
■ The entire arm is prepared and then placed into a hydraulic arm holder (Spider Limb Positioner, Tenet Medical Engineering, Calgary, Canada) (FIG 4). This avoids the need for an assistant to hold the arm.

FIG 3 • A. An interscalene catheter is established preoperatively to provide muscle paralysis and pain control during the procedure as well as sustained pain control for 48 hours after the arthroscopic release. B. Passive range of motion is examined under anesthesia to guide the arthroscopic release. The scapula should be controlled with one of the examiner’s hands to avoid scapulothoracic motion.

FIG 4 • We use a hydraulic arm holder (Spider Limb Positioner, Tenet Medical Engineering, Calgary, Canada) to secure the arm and avoid the need for an assistant.
The challenging aspect of arthroscopic capsular release is entering the contracted joint while avoiding iatrogenic articular injury (TECH FIG 1A–C).

- We establish the posterior arthroscopic portal slightly higher than normal (TECH FIG 1D).
- An 18-gauge spinal needle is inserted into the joint and insufflated (usually 10 to 15 cc in a contracted joint) with sterile saline.
  - Entry into the joint can be confirmed by noting backflow of saline from the spinal needle.
  - This step ensures proper portal placement and also distends the joint, thus lessening the risk of iatrogenic articular injury (TECH FIG 1E).

- An incision is made where the needle was inserted using a #11 blade and the arthroscope sheath is advanced into the glenohumeral joint.
- Entry into the joint is confirmed with backflow of saline through the sheath.
- With the arthroscope posteriorly, a spinal needle is inserted lateral to the coracoid through the rotator interval immediately underneath the biceps and above the subscapularis.
- An incision is made with a #11 blade and a 6-mm cannula is then placed through this portal.
- A radiofrequency device is passed through the cannula and used to remove synovium and soft tissue that obscures the view (TECH FIG 1F).

**TECH FIG 1** - It is often difficult to enter a shoulder with significant capsular contraction and scarring. A. Entering at or above the biceps with the anterior cannula is typically possible. B. The biceps can be displaced inferiorly and the rotator interval can be ablated to relax the joint and allow further release inferiorly. C. Forced entry with poor visualization can result in significant osteochondral injury, as depicted in this image. HH, humeral head. D. The posterior portal (a) is established higher than normal to lessen the risk of iatrogenic articular damage. The lateral (b) and anterior (c) portals are established using the outside-in technique with an 18-gauge spinal needle. E. Sterile normal saline is injected into the gleno-humeral joint. This causes distention, which lessens the risk of iatrogenic articular damage and verifies the portal position. Backflow of saline through the spinal needle ensures entry into the joint as opposed to soft tissue. F. The anterior capsule is visualized by the arthroscope from the posterior portal and a radiofrequency device is placed through the cannula anteriorly to remove synovium and create a potential working space.

**ANTERIOR CAPSULAR RELEASE**

- Resection of contracted and thickened capsule can be done with a radiofrequency device, shaver, or arthroscopic punch.
- We prefer to use a hook-tipped radiofrequency device to avoid bleeding, resect in a controlled fashion, and benefit from the feedback of electrical stimulation to nearby muscles and nerves.
- An arthroscopic punch can be used once a leading edge in the capsule has been established (TECH FIG 2A,B).
In adhesive capsulitis, the capsule is often up to 1 cm thick compared with the normal 2 mm.

We resect the anterior capsule systematically.

The rotator interval capsule is noted between the biceps superiorly and the intra-articular subscapularis inferiorly. This comprises the superior glenohumeral and coraco-humeral ligaments (TECH FIG 2C).

We begin by cutting (ablating) the capsular tissue immediately inferior to the biceps tendon (TECH FIG 2D).

The capsular tissue is released inferiorly until the superior border of the subscapularis is identified, thus releasing the rotator interval and its contents (TECH FIG 2E).

A switching stick can then be used to bluntly dissect the capsule from the deep surface of the subscapularis to create a defined interval. This capsule represents the middle glenohumeral ligament (TECH FIG 2F).

The capsule overlying the subscapularis is then divided to the 6 o’clock position (TECH FIG 2G).

Gentle external rotation can place the capsule under additional tension and facilitate its resection.

The axillary nerve is not at risk as long as the subscapularis muscle is seen (see Fig 1C).

The shaver is introduced to resect the capsular tissue medially and laterally to provide a generous interval (10 mm) and discourage the healing of capsular tissue in a contracted position.

**POSTERIOR CAPSULAR RELEASE**

- Release of the posterior capsule is necessary in patients with global capsular contracture or isolated posterior capsular contracture, often seen in patients with “non-outlet” impingement symptoms as described by Warner.¹⁴
- The arthroscope is placed through the anterior 6-mm cannula.
- Inflow is attached to the anterior cannula.
- A switching stick is placed through the arthroscopic sheath posteriorly into the joint (TECH FIG 3A).
- A 6-mm cannula is exchanged for the arthroscope sheath over a switching stick posteriorly (TECH FIG 3B).
- The hook-tipped radiofrequency device is passed through the cannula and is used to release the posterior
capsule from just posterior to the long head of the biceps to the 8 o’clock position (TECH FIG 3C–E).
- In our experience, a release of the inferior capsule from 6 o’clock to 8 o’clock is unnecessary.
- A shaver is introduced and used to further resect tissue medially and laterally, leaving a 10-mm capsule-free interval. The capsule is intimate with the infraspinatus and the release should be terminated at the point at which muscle is encountered.

SUBACROMIAL AND SUBDELTOID BURSOSCOPY
- Subacromial and subdeltoid scarring and adhesions are common after prior rotator cuff repair and fracture fixation.
- In cases of adhesive capsulitis there is often a component of subacromial bursitis.
- The subacromial space and subdeltoid space are always evaluated for bursitis as well as dense adhesions.
- The arthroscope is passed into the subacromial space through the posterior portal immediately inferior to the posterior acromion.
- A 6-mm smooth cannula is placed through the anterior portal (TECH FIG 4A).
- A radiofrequency device is passed through the anterior cannula to meet the arthroscopic lens and a subacromial decompression is initiated until the space adjacent to the lateral deltoid is free of adhesions.
- A spinal needle can then be used to locate the position of a lateral portal.
- A lateral portal is made with a #11 blade and a 6-mm cannula is introduced into the subacromial space.
- The anterior and lateral cannulas can alternately be used to achieve an adequate subacromial decompression.
- It is essential to free the interval between the acromion and rotator cuff as well as laterally in the space between the deltoid and proximal humerus (TECH FIG 4B).
- An acromioplasty can be done if indicated, although it is not usually necessary in cases of primary adhesive capsulitis.
TECH FIG 4 • A. The arthroscope sheath and blunt obturator are passed as a unit through the subacromial space and out the previously made anterior portal. The arthroscope is exchanged for the obturator in the sheath and a 6-mm cannula is placed over the sheath and lens tip. Both are withdrawn into the subacromial together, enabling the radiofrequency device to begin work débriding thick soft tissue within view of the arthroscope. B. Scar and bursa are removed from the subacromial space and the subdeltoid space (*) using a shaver and radiofrequency device. Adhesions are released between the rotator cuff and the acromion and deltoid.

POSTRELEASE MANIPULATION UNDER ANESTHESIA

- Range of motion is evaluated before manipulation under anesthesia to determine which structures need additional release.
- A sterile dressing is applied and the drapes are removed so that the scapula can be stabilized.
- A manipulation after a capsular release requires far less force and therefore carries a lower risk of fracture.
- The scapula is stabilized with one hand while the surgeon’s other hand firmly grasps the humerus above the elbow (TECH FIG 5).
- Sequence of manipulation:
  - External rotation in adduction
  - Abduction
  - External rotation in abduction
  - Internal rotation in abduction
  - Flexion
  - Internal rotation in adduction

TECH FIG 5 • A gentle manipulation under anesthesia is done after arthroscopic release and once the drapes have been removed.

PEARLS AND PITFALLS

| Hemostasis | Visualization is essential during a capsular release. We routinely use epinephrine in our bags of saline. In addition, we rely on the use of a radiofrequency device and limit the use of a shaver and arthroscopic punch. |
| Difficulty entering the glenohumeral joint with the arthroscope | Distention of the joint with sterile normal saline through an 18-gauge spinal needle ensures correct position of the portal. |
| | Typically the joint can be entered superiorly at the level of the biceps and initial release of the interval should relax the joint, allowing improved visualization. |
The following sequence can help gain access to the subacromial space, which facilitates safe decompression and lysis of adhesions:
1. The arthroscope sheath (with obturator) is passed through the posterior portal adjacent to the posterior acromion toward the anterior portal.
2. With the sheath adjacent to the acromion, the sheath and obturator are passed through the existing anterior portal.
3. The obturator is removed and the arthroscope secured in its sheath (lens and tip of scope exiting out of anterior portal).
4. The 6-mm cannula is placed over the tip of the sheath.
5. In a controlled fashion, the arthroscope is withdrawn into the subacromial space while the cannula is maintained on the tip of the sheath and passed into the subacromial space.
6. A radiofrequency device can be placed in the cannula as it is backed off the sheath by 1 to 2 mm.
7. The arthroscope can now visualize the radiofrequency device in a controlled and reproducible fashion to allow safe decompression instead of relying on blind navigation in dense scar and bursa.

POSTOPERATIVE CARE
- Immediately after surgery, the arm is placed in a simple sling and the shoulder in a cryotherapy sleeve.
- The patient is admitted for 48 hours and a continuous infusion of 0.1% bupivacaine is administered through the previously placed interscalene catheter at 10 to 20 cc per hour based on the pain level.
- Passive range of motion in all planes is initiated on the morning of the first postoperative day by the physical therapists. This is done twice a day.
- The patient is discharged on the afternoon of the second postoperative day after the indwelling catheter is removed.
- A simple sling for comfort is worn on discharge, but the patient is encouraged to use the operative arm for activities of daily living.
- After discharge, the patient immediately begins outpatient physical therapy to include stretching and water therapy whenever possible:
  - Five days a week for 2 weeks
  - Three days a week for 2 weeks
  - At 1 month, therapy regimen is transitioned to home program.
- Strengthening is initiated with elastic bands and weights only when range of motion is achieved. We prefer no strengthening until full range of motion is achieved.

OUTCOMES
- Multiple studies have shown the efficacy of arthroscopic capsular release for shoulder stiffness.
- In one study with an average of 33 months of follow-up, final motion at latest follow-up was 93% of the opposite side compared to 41% preoperatively, with a significant improvement in reported health status (SF-36) and ability to use the arm functionally.
- Warner et al11 found significant gains in range of motion (within 7 degrees of the values for the normal contralateral shoulder) in 23 patients with idiopathic adhesive capsulitis treated by arthroscopic release. All patients had either no pain or only occasional mild pain with forceful use of the shoulder.
- Warner et al14 found significant gains in range of motion in all planes in 11 patients with postsurgical stiffness who underwent either an anterior or combined anterior and posterior arthroscopic capsular release after failed nonoperative treatment.
- “Non-outlet” impingement with an associated posterior capsular contracture has been effectively treated by arthroscopic posterior capsular release with an average improvement of internal rotation at 90 degrees of abduction of 37 degrees and alleviation of pain in all but one of the nine patients studied.12

Beaufils et al1 showed that arthroscopic capsular release is effective at improving range of motion regardless of the cause of a stiff shoulder, although releases for postsurgical stiffness are less likely to alleviate pain than those done for adhesive capsulitis.

COMPLICATIONS
- Axillary nerve injury
- Rotator cuff tendon disruption
- Iatrogenic chondral injury
- Fracture or dislocation during manipulation under anesthesia
- Recurrence of stiffness

REFERENCEs
DEFINITION
■ Several terms have been used to describe the elements of scapulothoracic bursitis and crepitus, such as snapping scapula, washboard syndrome, scapulothoracic syndrome, and rolling scapula.
■ The first description of scapulothoracic crepitus is credited to Boinet in 1867.¹
■ By 1904, Mauclaire⁵ had described three subclasses—froissement, frottement, and craquement—depending on the loudness and character of the sound.
■ Milch⁶ and then Kuhn et al⁴ added to the understanding by differentiating sounds of soft tissues (frottement) from those arising from an osseous lesion (craquement or crepitus).

ANATOMY
■ Major bursae
  ▪ Infraserratus bursa located between the serratus anterior muscle and the chest wall
  ▪ Supraserratus bursa located between the subscapularis and the serratus anterior muscles
■ Minor bursae
  ▪ Not consistently identified on cadaveric or clinical studies
  ▪ Adventitial in nature; thought to arise secondary to abnormal biomechanics of the scapulothoracic joint
  ▪ Superomedial angle of the scapula
  ▪ Infraserratus
  ▪ Supraserratus
  ▪ Spine of scapula
  ▪ Trapezioid
  ▪ Inferior angle of scapula
  ▪ Infraserratus

PATHOGENESIS
■ Scapulothoracic bursitis can be caused by atrophied or fibrotic muscle, anomalous muscle insertions, or elastofibroma (rare benign soft tissue tumor located on the chest wall).
■ Osteochondromas and malunited fractures of the ribs or scapula can also cause pathology in this articulation.
■ Infectious causes include tuberculosis or syphilis.
■ The tubercle of Luschka is a prominence at the superomedial aspect of the scapula that can be excessively hooked and can cause altered biomechanics.
■ Scoliosis or thoracic kyphosis can contribute to scapulothoracic crepitus.
■ Unrelated disorders include cervical radiculopathy, glenohumeral pathology, and periscapular strain.

NATURAL HISTORY
■ Scapulothoracic disorders are often associated with repetitive overhead activities or with a history of trauma.
■ Constant motion leads to inflammation and a cycle of chronic bursitis and scarring.
■ Mechanical impingement and pain with motion are a result of tough fibrotic tissue, furthering the inflammatory cycle.

PATIENT HISTORY AND PHYSICAL FINDINGS
■ Repetitive overhead activities or trauma
■ Palpable or audible crepitus over the involved area
■ Occasionally bilateral or positive family history
■ Localized tenderness over the inflamed area is most common.
■ Superomedial border is the most commonly affected area.
■ Inferior pole is also a common site of pathology.
■ Pseudowinging (nonneurologic etiology) may result from fullness over the involved area and compensation of scapular mechanics due to pain.
■ Crepitus alone, without pain, may be physiologic and not warrant treatment.

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ Tangential scapular views to identify bony anomalies
■ Computed tomography is controversial but can be helpful if osseous lesions are suspected and plain radiographs are normal.
■ Magnetic resonance imaging (MRI) is also controversial but can identify the size and location of bursal inflammation.
■ Injection of a corticosteroid and local anesthetic is helpful to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS
■ Atrophied, fibrotic muscle or anomalous muscle
■ Malunited rib or scapular fracture
■ Mass (eg, elastofibroma, osteochondroma)
■ Infection (ie, tuberculosis, syphilis)
■ Scoliosis or kyphosis
■ Cervical spine radiculopathy
■ Glenohumeral disease

NONOPERATIVE MANAGEMENT
■ Rest
■ Nonsteroidal anti-inflammatory
■ Activity modification
■ Physical therapy
  ▪ Local modalities
  ▪ Periscapular strengthening, emphasizing subscapularis and serratus anterior
■ Postural training
■ Figure 8 harness for kyphosis
■ Injection may be of benefit for both diagnosis and treatment.

SURGICAL MANAGEMENT
■ Indicated for patients who have failed to respond to conservative therapy
■ Open treatment
Chapter 16  ARTHROSCOPIC TREATMENT OF SCAPULOTHORACIC DISORDERS

135

■ Has been used successfully in treatment of both bursitis\(^7,9\) and crepitus\(^6,8\)
■ Requires fairly large exposure and subperiosteal dissection of the medial musculature, with repair back to bone after debridement of pathologic tissue is accomplished
■ Arthroscopic treatment
■ Minimizes morbidity of the exposure and facilitates early rehabilitation and return to function

Preoperative Planning
■ If a bony mass is detected, computed tomography findings will help guide the planned resection.

Positioning
■ The patient is placed in the prone position, with the arm behind the back in extension and internal rotation (the so-called chicken wing position; FIG 1).

Approach
■ Decisions regarding open versus arthroscopic treatment for these disorders should be based on surgeon experience and comfort level.

POSTOPERATIVE CARE
■ Sling for comfort
■ Gentle passive motion immediately
■ Active and active-assisted motion and isometric exercises are started at 4 weeks postoperatively.
■ Periscapular strengthening starts at 8 weeks postoperatively.

OUTCOMES
■ No large series of arthroscopic treatment have been published.
■ Several smaller series have reported favorable outcomes after arthroscopic surgery.\(^2,3\)

COMPLICATIONS
■ Pneumothorax
■ Infection
■ Inadequate resection, recurrence of symptoms

FIG 1 • The arm behind the back in extension and internal rotation: the “chicken wing” position.

Preoperative Planning
• If a bony mass is detected, computed tomography findings will help guide the planned resection.

Positioning
• The patient is placed in the prone position, with the arm behind the back in extension and internal rotation (the so-called chicken wing position; FIG 1).

Approach
• Decisions regarding open versus arthroscopic treatment for these disorders should be based on surgeon experience and comfort level.

POSTOPERATIVE CARE
• Sling for comfort
• Gentle passive motion immediately
• Active and active-assisted motion and isometric exercises are started at 4 weeks postoperatively.
• Periscapular strengthening starts at 8 weeks postoperatively.

OUTCOMES
• No large series of arthroscopic treatment have been published.
• Several smaller series have reported favorable outcomes after arthroscopic surgery.\(^2,3\)

COMPLICATIONS
• Pneumothorax
• Infection
• Inadequate resection, recurrence of symptoms

ARTHROSCOPIC PORTALS

The initial “safe” portal is 2 cm medial to the medial scapular edge at the level of the scapular spine, between the chest wall and serratus anterior (TECH FIG 1A).
• Avoids dorsal scapular nerve and artery
• The space is distended with 150 mL saline via spinal needle and then the portal is created.
• After insertion of a 4.0-mm 30-degree arthroscope into the first portal, a second “working” portal is established under direct visualization (TECH FIGS 1B and 1D).

It is placed about 4 cm inferior to the first portal.
• A 6-mm cannula is inserted into this portal.
• An additional superior portal can be placed as described by Chan et al\(^1\) (TECH FIG 1C).
• Portals superior to the scapular spine place the dorsal scapular neurovascular structures, accessory spinal nerve, and transverse cervical artery at risk, however.

FIG 1 • The arm behind the back in extension and internal rotation: the “chicken wing” position.

Preoperative Planning
• If a bony mass is detected, computed tomography findings will help guide the planned resection.

Positioning
• The patient is placed in the prone position, with the arm behind the back in extension and internal rotation (the so-called chicken wing position; FIG 1).

Approach
• Decisions regarding open versus arthroscopic treatment for these disorders should be based on surgeon experience and comfort level.

POSTOPERATIVE CARE
• Sling for comfort
• Gentle passive motion immediately
• Active and active-assisted motion and isometric exercises are started at 4 weeks postoperatively.
• Periscapular strengthening starts at 8 weeks postoperatively.

OUTCOMES
• No large series of arthroscopic treatment have been published.
• Several smaller series have reported favorable outcomes after arthroscopic surgery.\(^2,3\)

COMPLICATIONS
• Pneumothorax
• Infection
• Inadequate resection, recurrence of symptoms

ARTHROSCOPIC PORTALS

The initial “safe” portal is 2 cm medial to the medial scapular edge at the level of the scapular spine, between the chest wall and serratus anterior (TECH FIG 1A).
• Avoids dorsal scapular nerve and artery
• The space is distended with 150 mL saline via spinal needle and then the portal is created.
• After insertion of a 4.0-mm 30-degree arthroscope into the first portal, a second “working” portal is established under direct visualization (TECH FIGS 1B and 1D).

It is placed about 4 cm inferior to the first portal.
• A 6-mm cannula is inserted into this portal.
• An additional superior portal can be placed as described by Chan et al\(^1\) (TECH FIG 1C).
• Portals superior to the scapular spine place the dorsal scapular neurovascular structures, accessory spinal nerve, and transverse cervical artery at risk, however.

FIG 1 • The arm behind the back in extension and internal rotation: the “chicken wing” position.
**RESECTION**

- A methodical approach to resection is needed because there are minimal anatomic landmarks.
- Radiofrequency ablation and motorized shaving are used (TECH FIG 2A,B).
- The surgeon proceeds medial to lateral and inferior to superior.
- Spinal needles can be used to outline the medial border of the scapula (TECH FIG 2C,D).
- Switching portals and the use of a 70-degree arthroscope may be necessary (TECH FIG 2E,F).
- The superomedial angle of the scapula is identified by palpation through the skin.
- Radiofrequency is used to detach the conjoined insertion of the rhomboids, levator scapulae, and supraspinatus from the bone.
- A partial scapulectomy is performed using a motorized shaver and burr.
- The arm should then be placed through a range of motion to assess the resection.

**TECH FIG 2 • A,B.** Resection and débridement of the scapula. C,D. The spinal needle is used as a guide to the medial border of the scapula. E,F. Final débridement.

**PEARLS AND PITFALLS**

| Portal placement | The surgeon should consider the neurovascular structures and the thoracic structures. |
| Portal placement | The surgeon should enter parallel to the ribs and use a spinal needle to localize the portals. |
| Portal placement | More inferiorly placed portals are safer because the dorsal scapular nerve arborizes terminally. |

| Visualization | Predistention |
| Visualization | Epinephrine for vasoconstriction |
| Visualization | Appropriate pump pressure |
| Visualization | The surgeon should work expeditiously. |

| Bursectomy | Inadvertent thoracotomy is avoided. |
| Bursectomy | A complete bursectomy is performed. |
| Bursectomy | The surgeon should avoid perforating the subscapularis muscle medially (bleeding). |

| Partial scapulectomy | Preoperative planning with computed tomography or three-dimensional computed tomography |
| Partial scapulectomy | Anatomy is localized with a spinal needle. |
| Partial scapulectomy | Adequate resection is performed. |

Arthroscopic Débridement and Glenoidplasty for Shoulder Degenerative Joint Disease

Christian J.H. Veillette and Scott P. Steinmann

DEFINITION

- Osteoarthritis (OA) is a degenerative disorder of synovial joints characterized by focal defects in articular cartilage with reactive involvement in subchondral and marginal bone, synovium, and para-articular structures.1,10
- Patients with degenerative joint disease (DJD) of the shoulder often have coexisting pathology, including bursitis, synovitis, loose bodies, labral tears, osteophytes, and articular cartilage defects.2,3,9
- Arthroscopic débridement may be a reasonable treatment option in these patients after conservative methods have been unsuccessful and when joint replacement is not desired.1
- Historically, patients who have early OA in whom concentric glenohumeral articulation remains with a visible joint space on the axillary radiograph are candidates for arthroscopic débridement.14
- Patients with severe glenohumeral arthritis for whom shoulder arthroplasty is not ideal, such as young or middle-aged patients and older patients who subject their shoulders to high loads or impact, remain an unresolved clinical problem and are potential candidates for arthroscopic techniques.1
- There are four basic options for arthroscopic treatment in a patient with DJD of the shoulder:
  - Glenohumeral joint débridement
  - Capsular release
  - Subacromial decompression
  - Glenoidplasty
- Choosing which of these four options to perform on a shoulder with DJD depends on the degree of arthritis and the skill, philosophy, and experience of the surgeon.1
- The goal of arthroscopic débridement is to provide a period of symptomatic relief rather than reverse or halt the progression of OA.

ANATOMY

- The normal head shaft angle is about 130 degrees, with 30 degrees of retroversion.4
- The articular surface area of the humeral head is larger than that of the glenoid, allowing for large normal range of motion.4
- Glenoid version, the angle formed between the center of the glenoid and the scapular body, averages 3 degrees and is critical for stability.4
- The glenoid fossa provides a shallow socket in which the humeral head articulates. It is composed of the bony glenoid and the glenoid labrum.4
- The labrum is a fibrocartilaginous structure surrounding the periphery of the glenoid. The labrum provides a 50% increase in the depth of the concavity and greatly increases the stability of the glenohumeral joint.4
- The glenoid had an average depth of 9 mm in the superoinferior direction and 5 mm in the anteroposterior direction with an intact labrum.6,8

PATHOGENESIS

- OA may be classified as primary, when there is no obvious underlying cause, or secondary, when it is preceded by a predisposing disorder.1
- Pathology in patients with glenohumeral OA includes a degenerative labrum, loose bodies, osteophytes, and articular cartilage defects in addition to synovitis and soft tissue contractures.1
- The disease process in OA of the shoulder parallels that of other joints. Degenerative alterations primarily begin in the articular cartilage as a result of either excessive loading of a healthy joint or relatively normal loading of a previously disturbed joint.12
- Progressive asymmetric narrowing of the joint space and fibrillation of the articular cartilage occur with increased cartilage degradation and decreased proteoglycan and collagen synthesis.12
- Subchondral sclerosis develops at areas of increased pressure as stresses exceed the yield strength of the bone and the subchondral bone responds with vascular invasion and increased cellularity.
Physical examination should include the following:

- Cystic degeneration occurs owing to either osseous necrosis secondary to chronic impaction or the intrusion of synovial fluid.
- Osteophyte formation occurs at the articular margin in non-pressure areas by vascularization of subchondral marrow, osseous metaplasia of synovial connective tissue, and ossifying cartilaginous protrusions.
- Fragmentation of these osteophytes or of the articular cartilage itself results in intra-articular loose bodies. In late stages, complete loss of articular cartilage occurs, with subsequent bony erosion.
- Posterior glenoid erosion is predominant, leading to increased retroversion of the glenoid and predisposing to subluxation and reduction of the humeral head, causing symptoms of instability.

**NATURAL HISTORY**

- Information on the natural history of OA in individuals and its reparative processes is limited.
- Progression of OA is considered generally to be slow (10 to 20 years), with rates varying among joint sites.  
- No specific longitudinal studies exist on the progression of shoulder OA.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Typical history for patients with OA is progressive pain with activity over time.
- In early stages, pain is related to strenuous or exertional activities but over time it progresses to activities of daily living. In later stages, pain occurs at rest and at night.
- Pain may be mistaken for impingement syndrome early in the disease process or rotator cuff disease when symptoms occur in the presence of good motion.
- Progression of the disease often leads to secondary capsular and muscular contractures with loss of active and passive motion.
- Mechanical symptoms such as catching and grinding are often reported with use of the shoulder.
- The pain of shoulder OA can be divided into three types:
  - Pain at extremes of motion: due to osteophytes and stretching of the inflamed capsule and synovium
  - Pain at rest: due to synovitis (pain at night is not the same as pain at rest and may be due to awkward positions or increased pressure)
  - Pain in the mid-arc of motion: usually associated with crepitus and represents articular surface damage
- Physical examination should include the following:
  - Range of motion: Loss of both active and passive motion consistent with soft tissue contractures. In patients with preserved passive motion but loss of active motion, rotatory cuff pathology should be ruled out.
  - Compression–rotation test: Pain during mid-arc of motion is a potentially poor prognostic indication.
  - Neer test and Hawkins test: Often patients with OA have positive impingement signs related to articular lesions in the glenohumeral joint or to the synovitis in the joint and subacromial pathology.
  - Supraspinatus evaluation: Weakness may reflect associated supraspinatus tear. Patients with OA may have weakness related to pain inhibition on resistance.

- Infraspinatus and teres minor evaluation: Weakness may reflect associated posterior rotator cuff tear. Patients with OA may have weakness related to pain inhibition on resistance.
- Subscapularis evaluation: Weakness may reflect associated subscapularis tear. Patients with OA may have weakness related to pain inhibition on resistance.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A standard shoulder series consisting of a true anteroposterior view in the scapular plane, a scapular lateral view, and an axillary view should be obtained on all patients before surgical intervention (FIG 2A,B).
- Classic findings of glenohumeral OA are joint space narrowing, subchondral sclerosis, subchondral cysts, and osteophyte formation.
- Posterior wear of the glenoid is often noted on the axillary view in later stages of the disease.
- Magnetic resonance imaging (MRI) is more sensitive for the diagnosis of early-stage OA than are plain radiographs and can identify concurrent soft tissue pathology.
- Up to 45% of patients with grade IV chondral lesions can have no radiographic (MRI or plain radiograph) evidence of OA on preoperative imaging.  
- Computed tomography (CT) scanning provides improved visualization of the bony glenoid, osteophytes, and loose bodies (FIG 2C).
- Three-dimensional reconstructions provide an excellent visual representation of the biconcave glenoid to assist in preoperative planning (FIG 2D).

**DIFFERENTIAL DIAGNOSIS**

- Impingement syndrome
- Adhesive capsulitis
- Superior labral anterior to posterior (SLAP) lesions
- Rotator cuff tears
- Instability

**NONOPERATIVE MANAGEMENT**

- Standard nonoperative modalities, such as nonsteroidal anti-inflammatory medications, steroid injections, and physical therapy, should be explored before arthroscopic techniques.

**SURGICAL MANAGEMENT**

- Current indications for arthroscopic osteocapsular arthroplasty and glenoidplasty are patients with the following:
  - Moderate to severe glenohumeral OA
  - A biconcave glenoid
  - Moderate to severe pain causing functional impairment that has failed to respond to nonsurgical treatment
  - Painless crepitus with glenohumeral motion during joint compression
- Patient must have a relative contraindication to total shoulder arthroplasty such as age younger than 50 years, excessive physical demands, or unwillingness to consider shoulder replacement.
- Age and prior successful total shoulder arthroplasty on the contralateral shoulder are not contraindications.
Glenoidplasty is performed if there is a biconcave glenoid from posterior wear and involves recontouring the surface to recreate a single concavity.

- The rationale is to restore the position of the humeral head, thus reducing posterior subluxation, increasing the surface area of articulation, decreasing joint pressure, and relaxing the anterior soft tissues.

- Subacromial decompression preoperative examination and intraoperative arthroscopic findings implicate the subacromial space as source of pain.
- A thickened bursa consistent with chronic bursitis has been documented, and several authors advocate a soft tissue decompression, at a minimum.\(^3,15\)
- Bleeding from the undersurface of the acromion may lead to subacromial fibrosis and loss of motion. Therefore, routine subacromial decompression is not recommended.

Preoperative Planning

- The surgeon should review high-quality radiographs, especially the axillary view if glenoidplasty will be performed, to plan the increase in depth of the glenoid required to convert the biconcave glenoid back to a single concavity.
- The surgeon examines the range of motion under anesthesia and compares it to the opposite side.

Positioning

- The patient is placed in the beach-chair or lateral decubitus position after regional anesthesia (interscalene block) or general anesthesia is obtained.
- Unobstructed access to the anterior and posterior aspects of the shoulder is imperative (FIG 3).
- A potential disadvantage of the lateral decubitus position is the need to take the arm out of traction periodically to check the range of motion after capsular resection.

- If working in the area of the axillary nerve, the semi-abducted position used in the lateral decubitus position tends to bring the axillary nerve closer to the capsule.

Approach

- A standard midposterior arthroscopic portal is established in usual fashion.
- A standard anterior portal is made using an 18-gauge spinal needle under direct arthroscopic vision to locate the position in the rotator interval.
- Additional portals that are often required include a midlevel anterior portal (adjacent to the superior border of the subscapularis) for osteophyte removal and a posteromedial portal for placement of a retractor to clear the axillary pouch from the humeral head and neck.
- It is helpful to place both the posterior and anterior portals a bit more inferior than usual to allow easier access to the inferior aspect of the joint.
**DIAGNOSTIC ARTHROSCOPY**

- A standard 15-point assessment of the arthroscopic glenohumeral anatomy as outlined by Snyder\textsuperscript{11} is performed.
- Typical findings include extensive synovitis, especially on the undersurface of the rotator cuff, fraying of the labrum, and fibrillation or loss of articular cartilage.

**SYNOVECTOMY AND DÉBRIDEMENT**

- A complete systematic synovectomy is performed using a combination of an arthroscopic thermal device to minimize bleeding and a full-radius shaver (4.8 or 5.5 mm).
  - The surgeon begins by removing synovium from the anterosuperior aspect of the joint, moving posteriorly and then inferiorly into the axillary recess and finally the posterior inferior synovium.
  - A full-radius shaver is used to débride the fraying labrum and remove loose bodies and unstable chondral flaps.
- Working space in the inferior axillary pouch is markedly increased after removal of the inferior osteophyte and permits improved visibility of the inferior capsule and safer performance of partial capsulectomy.

**CAPSULECTOMY AND RELEASE**

- The surgeon removes impinging osteophytes, especially any inferior osteophyte from the humeral head, and performs appropriate capsular or interval releases to regain passive motion.
  - An efficient way to visualize and remove inferior osteophytes is to view from the anterior portal using a standard 30-degree arthroscope and then establish a posterior inferior working portal. The shaver or burr can then be brought in posteriorly to remove capsule or osteophytes.
  - The inferior humeral osteophyte is removed first through the posterior inferior working portal using a 4.0-mm hooded burr (which protects the inferior capsule and the axillary nerve) beginning posteriorly and moving anteriorly.
  - The humerus can be internally rotated to deliver the osteophyte and improve positioning of the instrument.
- The inferior capsular attachment to the humeral head should be identified and used as a landmark to recreate the normal architecture of the humerus.
  - A 5.5-mm full-radius shaver is useful to débride any loose bony fragments and soft tissues from the burr.
  - Suction on the instruments should be avoided to decrease the likelihood of unintentional damage to the axillary nerve from soft tissue drawn into the instrument.
  - A curved curette may be required to reach around and remove the anterior aspect of the inferior osteophyte.
  - Fine contouring may be done with the shaver or hand rasps as necessary.
  - Working space in the inferior axillary pouch is markedly increased after removal of the inferior osteophyte and permits improved visibility of the inferior capsule and safer performance of partial capsulectomy.
  - A full-radius shaver is placed through the posterior portal and used to create a capsulotomy in the posterior aspect of the inferior capsule (in the right shoulder at the 7 o’clock position) adjacent to the glenoid rim.
  - The plane between the inferior capsule and underlying soft tissues is then developed with a wide duck-billed basket punch moving from a posterior to an anterior direction. The shaver is then used to widen the resection.
  - The capsulectomy should be performed as close to the glenoid rim as possible to minimize the risk to the axillary nerve, which should be identified and protected with a probe after the 6 o’clock position is reached.
  - A partial capsulectomy is then performed anteriorly, ante-rior osteophytes are removed, and the capsule is removed from the rotator interval (TECH FIG 1).

**TECH FIG 1** Osteocapsular arthroplasty. Osteophyte removal is usually best done before resection of the capsule and primarily involves working in the inferior aspect of the glenohumeral joint. A. Inferior osteophytes are best viewed from the anterior portal using a standard 30-degree arthroscope, and then the shaver or burr can be brought in from a posterior inferior working portal to remove capsule or osteophytes. (continued)
This can be done viewing from a posterior portal and using an anterior portal to direct a cautery-radiofrequency device or a shaver to release the anterior capsule from the anterior glenoid surface.

Any residual anteroinferior capsule can be resected from the anterior portal to connect with the inferior capsulectomy.

The direct posterior capsule is not generally removed, just as it is not typically resected during a total shoulder replacement. The posterior capsule is often lax from the posterior subluxation and posterior glenoid wear seen in osteoarthritis.

GLENOIDPLASTY

Anterior and posterior portals are used to perform the procedure, and the biconcave shape of the glenoid can best be visualized by looking inferiorly from the anterior portal (TECH FIG 2A).

A full-radius shaver is used to remove the remaining cartilage from the anterior glenoid facet (TECH FIG 2B).

The central vertical bony ridge is then removed using a 4-mm round burr moving from anterior to posterior in a superior to inferior direction.

The glenoid is divided into quarters and the superior half is contoured first to allow comparison with the prior biconcave glenoid (TECH FIG 2C).

The view of the glenoid can be alternated from front to back, and once a single concave surface has been established, a large hemispherical hand rasp can be used to deepen and smooth the surface (TECH FIG 2D).

The glenoidplasty is assessed intraoperatively by performing a compression-rotation test and palpating for crepitus and assessing the rotation of the humerus on the new glenoid surface arthroscopically.
SUBACROMIAL DECOMPRESSION

- Using standard portals to explore the subacromial space, a shaver or cautery–radiofrequency probe is placed above the rotator cuff, and any thickened bursa is removed.
- Bursal-sided fraying or tearing of the rotator cuff can also be addressed at the same time.
- There is usually no need to perform an acromioplasty, but if a minor spur of the acromion is encountered it can be resected. The corococacromial ligament should be preserved.

PEARLS AND PITFALLS

| Preoperative planning | Computed tomography scan with three-dimensional reconstructions to visualize biconcave glenoid from anticipated arthroscopic views |

| Débridement | Complete, systematic synovectomy with removal of all traces of synovitis |
|            | Thermal ablation device is helpful for removal of synovitis and simultaneous control of bleeding. |
|            | Removal of inferior osteophyte on humeral head greatly increases working space for inferior capsulectomy. |
|            | Anterior capsulectomy is performed with arthroscope posterior and instruments anterior. |
|            | Inferior capsulectomy is performed with arthroscope anterior and instruments posterior. |
|            | Capsulectomy should be performed as close to the glenoid rim as possible to minimize the risk to the axillary nerve. |

| Glenoidplasty | The surgeon removes anterior cartilage and defines the central bony ridge. |
|              | Glenoid is divided into four quadrants. Glenoidplasty starts on the inferior half to allow comparison with the biconcave glenoid. |
|              | Assistant must translate the humeral head posteriorly when working on the anterior aspect of the glenoid, and vice versa when working posteriorly. |
|              | A curved hand rasp is used to fine-tune the glenoid contour. |

POSTOPERATIVE CARE

- Full, unrestricted passive and active assisted range of motion is initiated on the first postoperative day.
- Patients with an osteocapsular arthroplasty and glenoidplasty have an indwelling glenohumeral catheter for postoperative analgesia and stay in the hospital overnight.
- Most patients benefit from a structured therapy program supervised by a trained therapist to encourage full passive and active motion.
- The patient begins isometric strengthening immediately and progresses to isotonic exercises as tolerated.
- Patients should be allowed to go back to work as soon as they are comfortable.

OUTCOMES

- Ellman et al\(^1\) showed the benefit of arthroscopic débridement of the glenohumeral joint in 18 patients who underwent initial shoulder arthroscopy for impingement syndrome but were shown at operation to have coexisting glenohumeral DJD that was not evident on preoperative clinical and radiographic evaluation.
- Weinstein et al\(^14\) reported an 80% satisfactory improvement in 25 patients with early OA treated with arthroscopic débridement. Cameron et al\(^2\) reported on 61 patients with grade IV chondral lesions of the shoulder treated with arthroscopic débridement with or without capsular release. Overall, 88% of patients had a satisfactory outcome.
Pain relief is not related to the radiographic stage of arthritis or the location of the lesion. However, return of pain and failure are associated with osteochondral lesions greater than 2 cm in diameter. Kelly et al presented the results on 14 patients with a mean age of 50 years treated with osteocapsular arthroplasty and glenoidplasty. Early follow-up at 3 years showed an 86% rate of improvement, and 92% agreed that the surgery was worthwhile. No complications were reported and there was no evidence of medial migration of the humerus.

COMPLICATIONS

None of the previously published studies on arthroscopic treatment of glenohumeral OA reported complications. Ogilvie-Harris and Wiley reported 15 complications in 439 patients (3%) treated with arthroscopic surgery of the shoulder. Medial migration of the humerus after glenoidplasty and inability to perform glenoid resurfacing during total shoulder replacement has not been encountered.

REFERENCES

DEFINITION
- Elbow arthroscopy involves the use of an arthroscope to examine the interior of the elbow joint and provides the opportunity to perform minimally invasive diagnostic and therapeutic procedures.
- Elbow arthroscopy has evolved to allow the definitive care of more than a dozen complex elbow conditions.
- Despite an expanded understanding of the surrounding neurovascular anatomy, essential portal placement for access to the elbow joint continues to present a level of risk for injury that exceeds that seen in other joints.
- The safe application of this treatment modality requires that the surgeon have a solid grasp of the relative anatomy, fellowship or laboratory training in treatment techniques, experience as an arthroscopist, and an objective assessment of his or her own level of skill.

ANATOMY
- Neurovascular injury risk is relatively high and a three-dimensional grasp of elbow anatomy is essential for safe and successful elbow arthroscopy. Miller et al. showed that the bone-to-nerve distances in the 90-degree-flexed elbow increased with joint insufflation an average of 12 mm for the median nerve, 6 mm for the radial nerve, and 1 mm for the ulnar nerve.
- The capsule-to-nerve distance changes very little with insufflation, however, and the protective effect of insufflation is lost when the elbow is in extension.
- Miller et al. also showed that in the insufflated, 90-degree-flexed elbow, both the radial and median nerves passed within 6 mm of the joint capsule and that the radial nerve was on average 3 mm closer to the capsule than the median nerve. The ulnar nerve was essentially on the capsule.
- Others have also shown the close proximity of the radial nerve to the joint capsule and stressed the greater risk to this nerve during both portal placement and capsular resection.
- Stothers et al. emphasized the importance of elbow flexion during portal placement and showed that the portal-to-nerve distances decreased an average of 3.5 to 5.1 mm laterally and 1.4 to 5.6 mm medially when the elbow was in extension.
- For the distal anterolateral portal, the distance from the sheath to the radial nerve averaged 1.4 mm (range 0 to 4 mm) in extension and 4.9 mm (2 to 10 mm) in flexion.
- Field et al compared three anterolateral portals and reported a statistically significant difference in portal-to-radial nerve distance, with greater safety shown with the more proximal locations.
- Anatomic studies suggest three guidelines for neurovascular safety:
  - Portal placement is safer when the elbow is flexed 90 degrees than when it is in extension.
  - Maximal joint distention before portal placement increases the safety during placement by increasing the nerve-to-portal distance.

FIG 1 • A. Relative anatomy of the medial elbow and the arthroscopic portal sites: 1, standard anteromedial; 2, mid-anteromedial; and 3, proximal anteromedial. B. Relative anatomy of the lateral and posterior elbow and the arthroscopic portal sites: 1, distal anterolateral; 2, mid-antlerolateral; 3, proximal anterolateral; 4, direct posterolateral; 5, posterolateral; and 6, posterior central.
The nerve-to-portal distance is greater for the more proximal anterior portals than for the more distal anterior portals.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- This chapter does not address a specific condition but instead offers a broad view of the basic considerations and setup issues for a surgical treatment that may be applied to many different elbow problems.
- A complete review of the numerous clinical tests described for the diagnostic evaluation of the elbow would exceed the scope of this chapter.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Routine preoperative elbow radiographs should include a true lateral view, a standard anteroposterior (AP) view, and an AP view of both the distal humerus and proximal forearm when joint motion loss prevents full joint extension.
- Additional radiographic views include the cubital tunnel view, the posterior impingement view, the capitellum view, and the radial head view.
- The cubital tunnel view, an AP projection of the humerus with the elbow maximally flexed, provides a clear view of the medial epicondyle and cubital tunnel groove.
- The posterior impingement view is also an AP projection of the humerus with the elbow maximally flexed, but the humerus is rotated into 45 degrees of external rotation. This image offers better assessment of the posterior medial edge of the olecranon tip and the medial epicondyle apophysis.
- The capitellum view, an AP projection of the ulna with the elbow flexed 45 degrees, provides a tangential view of the capitellum for better evaluation of osteochondritis dissecans lesions.
- The radial head view is an oblique view of the 90-degree-flexed elbow with the beam passing between the ulna and the radial head. It allows for clear imaging of both the radial head and the radial-ulna interval.
- Although this point is sometimes argued, computed tomography is often useful when resection of intra-articular bone is considered as a part of contracture release arthroscopy.
- Magnetic resonance (MR) imaging in a closed high-field magnet with thin-section, optimized, high-spatial-resolution sequences may provide exceptional detail of the structures surrounding the elbow joint; however, MR arthrography, with either saline or gadolinium, will improve the assessment of intra-articular structures such as loose bodies.

**SURGICAL MANAGEMENT**

- The indications for elbow arthroscopy include the evaluation and treatment of septic arthritis, lateral synovial plica syndrome, systemic inflammatory arthritis, loose bodies, synovitis, osteochondritis dissecans (OCD), degenerative arthritis, posterior impingement, traumatic arthritis, trochlea chondromalacia, arthrofibrosis, lateral epicondyritis, joint contracture, postero-lateral rotatory instability, and olecranon bursitis.
- Treatment options for these conditions include diagnostic evaluation, loose body removal, synovial biopsy, partial or complete synovectomy, plica excision, extensor carpi radialis brevis tendon débridement, capsule release, capsulotomy, capsulectomy, exostosis excision, ulnohumeral arthroplasty, contracture release, chondroplasty, microfracture chondroplasty, percutaneous drilling or fixation of OCD lesions, capitellum osteochondral transplantation, radial head excision, internal fixation of fractures, lateral ulnar collateral ligament plication, ulnar nerve decompression, and finally olecranon bursctomy.
- The relative contraindications for elbow arthroscopy include recent joint or soft tissue infection, developmental changes, previous trauma or surgery that significantly alters the normal neurovascular, bony, or soft tissue anatomy of the elbow, extensive extracapsular heterotopic ossification, complex regional pain syndrome, and conditions that prevent distention of the elbow capsule.
- Previous ulnar nerve transposition usually requires exposure of the ulnar nerve before the creation of an anteromedial portal.

**Preoperative Planning**

- As with all medical conditions, the importance of the information gained from a careful and complete history and examination for establishing an accurate diagnosis cannot be overemphasized.
- Plain radiographs are also essential, but some authors suggest that computed tomography and MRI offer little in the preoperative assessment.
- In contrast, the exact location of intra-articular, capsular, and extra-articular bone, the thickness of the joint capsule, the integrity of the cartilage covering an OCD lesion, and the presence of stress fractures or loose bodies unseen on radiographs are a few examples of how additional imaging may directly or modify care.
- The surgeon should consider how associated procedures to be performed in conjunction with the arthroscopy will affect patient positioning and the possible need to reposition during the case.
- Fluoroscopy should be available when drilling, pinning, or internal fixation is considered.
- In addition to standard arthroscopic instrumentation, the preoperative plan should also consider the need for specialized instruments such as retractors and special biters for contracture release surgery and small-fragment-fixation devices for OCD or fracture care.
- Elbow arthroscopy may be done using either general or regional anesthesia.
- General anesthesia is typically preferred as it allows for complete muscle relaxation. Regional blockade is reserved for contracture release procedures where repeated manipulation and continuous passive motion is planned during the hospitalization.
- While regional anesthesia may be given before surgery, many surgeons prefer to wait until the status of the neurovascular structures is established in the recovery setting.
- Indwelling catheter regional anesthesia is described and sometimes recommended for contracture release procedures, but not all centers are comfortable or experienced with these techniques, and repeated regional anesthesia during the hospitalization appears to be equally effective.
- The use of ultrasound during injection may decrease the morbidity associated with regional anesthesia.
Positioning

- The four patient positions for elbow arthroscopy are the supine cross-body position, the supine suspended position, the lateral decubitus position, and the prone position.
  - While the latter two positions are most popular today, experience with one of the supine positions still offers advantages. For example, a surgeon who prefers the prone position may elect to use the supine cross-body position when arthroscopic and open procedures are combined, preventing the need for repositioning.

- **Supine cross-body position**
  - Arthroscopy in this position may be done with one of several commercially available arm-holding devices but is performed equally well with an assistant acting as the arm holder (FIG 2A).
  - Because the elbow is not rigidly stabilized in this position, complex procedures may be more challenging and present a greater level of risk for injury.
  - The supine cross-body position is most useful when a less demanding arthroscopic procedure is performed along with an open surgery.

- **Supine suspended position**
  - This position requires the use of a traction device from which the arm is hung. Capture of the hand or wrist is necessary, and finger traps on the index and long fingers work well in this regard (FIG 2B).
  - The elbow is not stabilized against either a post or pad, which allows considerable movement of the elbow beneath the hand.
  - Two potential disadvantages of this position are the unexpected withdrawal of the arthroscope from the freely swinging joint and the almost vertical position of the arthroscope during arthroscopy of the posterior compartment.

- **Lateral decubitus position**
  - This position for elbow arthroscopy is typically set up the same as for shoulder surgery except that the arm is draped across a padded horizontal post attached to the table (FIG 2C).
  - The advantage of this position over the supine positions is that a stable platform is created on which the upper arm rests. There is equal access to the anterior and posterior compartments.
  - The advantage of this position over the prone position becomes apparent when management of the airway is at issue. If prone positioning is a concern, such as in patients with a high body mass index or compromised lung volume, the case is probably best done in the lateral decubitus position.
  - One disadvantage of this position is that small patients, such as gymnasts with OCD lesions, are difficult to position lateral and still maintain full access to the arm.

![FIG 2 • Positioning. A. Left elbow draped in the supine cross-body position. An arthroscope is in the proximal anteromedial portal and a loose body is shown on the monitor. B. Left elbow draped in the supine suspended position. Sterile towels and elastic wrap are used to cover finger traps attached to the index and long fingers. C. Left elbow in the lateral decubitus position. D. Right elbow draped in the prone position. A roll of towels is placed between the upper arm and a shortened armboard aligned with the table. E. Right elbow draped over a shortened padded armboard.](image-url)
Whether the initial anterior portal should be medial or lateral is debatable but usually determined by surgeon preference and patient diagnosis. Good arguments may be made for either approach.\textsuperscript{1,9,13}

The second anterior portal may then be created with either outside-in or inside-out methods. We prefer to make the medial portal first and then create the lateral portal with an outside-in method.

**Instruments**

A standard 4.0-mm, 30-degree offset arthroscope may be used for virtually all elbow arthroscopic procedures. On rare occasion, both a 4.0-mm, 70-degree offset arthroscope and a 2.7-mm arthroscope may be helpful. Because it is often necessary to maintain the tip of the arthroscope just a few millimeters through the capsule, an arthroscope sheath without side flow ports is preferred and minimizes fluid extravasation into soft tissues.

Essential instruments include an 18-gauge spinal needle, a hemostat, a Wissinger rod, switching rods, and both standard and small mechanical shavers (FIG 3A,B).

Specialized instruments have recently become available from several sources and include a series of curved and straight arthroscopic retractors, curettes, and osteotomes. Hand biters, designed to resect the anterior capsule more safely, are very useful during contracture release surgery (FIG 3C).

**Prone position**

Many surgeons, because of the stability and access provided, prefer the prone position. However, careful attention to positioning is essential to avoiding complications (FIG 2D).

The airway must be secure and the face should be well padded.

Chest rolls are used to lift the chest and abdomen from the table, decreasing the airway pressure required for ventilation.

The knees are padded and the feet are elevated.

The nonoperative arm is placed on a well-padded arm board, with attention to the ulnar nerve, and the operative arm is allowed to hang over a shortened, padded armboard positioned along the side of the table (FIG 2E).

Pulses in all four extremities are confirmed.

After draping, a small roll of towels is placed beneath the upper arm to align the humerus in the coronal plane of the body and to allow the elbow to flex to 90 degrees.

**Approach**

The first arthroscopic portal is anterior except when the entire procedure is accomplished through posterior portals. Occult conditions may exist in the anterior compartment, and a complete diagnostic assessment of the joint requires anterior portals.
Chapter 18  ELBOW ARTHROSCOPY: THE BASICS

LIMB PREPARATION

- Setup and portal positions are shown in the supine cross-body position.
- After the administration of general anesthesia, the operative-arm shoulder is relocated to extend just over the edge of the surgical table, affording access to the whole extremity and limiting the reach required for the surgeon.
  - Both the shoulder and the entire arm are prepared and draped and a sterile tourniquet is applied as proximally as possible.
- After limb exsanguination, the tourniquet is elevated and an elastic compression wrap is applied tightly to the forearm, extending from distal to proximal and ending just distal to the radial head.
  - The elastic wrap will limit fluid extravasation into the subcutaneous tissues and the muscle compartments of the forearm and potentially decrease the risk of compartment syndrome.
- Landmarks about the elbow and the proposed arthroscopic portal sites are marked.
- Before portal placement, the joint is distended with saline using an 18-gauge spinal needle passed through the posterolateral “soft spot” (TECH FIG 1).
  - The “soft spot” is located at the center of the triangle formed by the olecranon prominence, the lateral epicondyle prominence, and the lateral margin of the radial head.
- Connector tubing attached to a 60-mL syringe allows an assistant to maintain joint distention during the creation of the initial portal without obstructing the surgeon’s access.

Order of Portal Placement

- Anterior or posterior
  - Neurovascular risk is the most important factor to be considered when determining the order of portal placement.
  - Soft tissue swelling and loss of the capacity to distend the joint would be expected after the creation of the posterior portals and would place both the median and radial nerves closer to the path of the anterior portals.
  - Most surgeons choose to begin the arthroscopy with the anterior portals.

ANTEROMEDIAL PORTALS

- There are three commonly described anteromedial portals: standard, mid, and proximal (TECH FIG 2A).
- The nerve at greatest risk for injury is the medial antebrachial cutaneous nerve. This risk diminishes when the depth of the portal incision avoids cutting the subcutaneous tissues.6
- Dissection to the flexor fascia with a blunt-tipped hemostat allows mobilization of the cutaneous nerves away from the portal for additional protection.
  - Up to six branches are described crossing the medial elbow, and on average at least one branch is within 1 mm (range 0 to 5 mm) of the portal (TECH FIG 2B).
  - Both the median nerve and the brachial artery are at risk during medial portal placement.
- Continuing the hemostat dissection to the medial joint capsule (TECH FIG 2C), introducing the arthroscope sheath with a blunt trocar, and finally penetrating the capsule with a sharp trocar will allow safe medial capsule penetration and avoid extracapsular arthroscopic placement.
- Some authors argue that sharp trocars have no role in elbow arthroscopy; however, blunt trocars are more inclined to penetrate the capsule laterally or, even less desirably, to remain extracapsular. Modifying a sharp trocar by blunting the tip provides a safe and effective compromise.

Medial or lateral

- The order is usually determined by surgeon preference and the nature of the conditions requiring treatment.
- The sheath-to-nerve distance for the mid-anteromedial portal averages 23 mm,5 that for the distal anterolateral portal averages 3 mm,5 and that for the proximal anterolateral portal averages 14.2 mm.5
- Because the nerve-to-sheath distance is greater for the anteromedial portals than for the anterolateral portals, it has been argued that the initial approach to the joint is safer when medial.
- Once the medial portal is established, the lateral portal can be made with an outside-in technique and an 18-gauge spinal needle11,12 or with an inside-out technique and a Wissinger rod.5
- Both methods are relatively safe techniques, but the outside-in method affords greater control of the angle into the joint and potentially greater access to the anterior humerus.
Standard Anteromedial Portal
- Andrews and Carson\(^2\) described the standard anteromedial portal as located 2 cm anterior and 2 cm distal to the prominence of the medial epicondyly. They reported that the median nerve-to-sheath distance was 6 mm.
  - The path of the portal penetrates the common flexor origin, as well as the flexor carpi radialis and the pronator muscles.
  - In some patients, the portal also penetrates the medial border of the brachialis muscle.
- Lynch et al\(^6\) showed that with joint distention and 90-degree elbow flexion, this portal averaged 14 mm from the median nerve. However, Stothers et al\(^1,12\) showed that the median nerve-to-sheath distance averaged only 7 mm (range 5 to 13 mm) and that the brachial artery-to-sheath distance was just 15 mm (range 8 to 20 mm).
- The standard anteromedial portal may be created with either medial (outside-in) or lateral (inside-out) methods. Some authors suggest that it is more safely created using the latter method with a rod exchange technique.
- Although this portal offers excellent visualization of the anterolateral contents of the elbow joint, it is now most commonly recommended as an accessory portal for capsular retractors.

Proximal Anteromedial Portal
- The proximal anteromedial portal, popularized by Poehling et al\(^1,10\) is described as 2 cm proximal to the prominence of the medial epicondyly and just anterior to the medial intermuscular septum.
  - Others have subsequently described this portal as up to 2 cm anterior to the septum.\(^9\)
  - The locations of both the septum and the ulnar nerve must be established before portal placement and the path of the portal must remain anterior to the septum.
  - Arthroscope sheath contact with the anterior humerus is advised to further protect the median nerve.\(^10\)
- In this location, at 90 degrees of flexion and with joint distention, the portal averages 12.4 mm (range 7 to 20 mm) from the median nerve, 18 mm from the brachial artery, 12 mm (range 7 to 18 mm) from the ulnar nerve, and 2.3 mm (0 to 9 mm) from the medial anterolateral cutaneous nerves.
- This portal also provides visual access to the lateral elbow joint structures, but viewing the superior capsular structures, the lateral capitellum, and the radiocapitellar joint space is limited compared to the standard anteromedial portal.\(^1,12\)

Mid-Anteromedial Portal
- A modification of the proximal anteromedial portal was described by Lindenfeld\(^5\) as located 1 cm proximal and 1 cm anterior to the prominence to the medial epicondyle.
  - The portal is directed distally into the center of the joint to preserve the protection afforded by the proximal location and was shown to average 22 mm from the median nerve.

ANTEROLATERAL PORTALS
- While at less risk for injury than the medial anterolateral cutaneous nerve, the anterior branch of the posterior antebibial nerve crosses the lateral elbow and may be injured during portal placement. Limiting the depth of the skin incision and using the arthroscope to cast a silhouette of the nerve may provide reasonable protection.
  - There are three anterolateral portal locations: distal, mid, and proximal (TECH FIG 3).

Distal Anterolateral Portal
- Andrews and Carson\(^2\) were first to describe an anterolateral portal and recommended placement 3 cm distal and
1 cm anterior to the prominence of the lateral epicondyle. Their work documented that the radial nerve averaged 7 mm from the arthroscope sheath when the elbow was flexed 90 degrees.

- Others have reported that the nerve-to-sheath distance was less, averaging only 3 to 4.9 mm,5,11,12 and that in extension this distance was just 1.4 mm.
- Field et al3 showed that Andrew and Carson’s recommendation located the portal near or directly over the radial head in all specimens studied, and that for smaller patients these measurements would potentially place the portal distal to the radial head.
- To lessen the risk of radial nerve injury, landmarks, rather than measurements, are used to determine that the portal is proximal to the radial head.3
- Because of safety concerns, this portal is much less commonly used than the more proximal portals and is typically reserved for a blunt retractor.
- An outside-in method is effective and probably safest.
  - With the elbow at 90 degrees, the forearm in slight pronation, and the joint maximally distended, an 18-gauge spinal needle is placed just anterior to the radial head and directed proximally toward the center of the radiocapitellar joint (TECH FIG 4).
  - A hemostat is then used to dissect through the capsule and a blunt-tipped retractor is introduced to mobilize the anterior capsule.
  - The arthroscope and working instruments are placed in more proximal portals.
  - Superficially, the anterior branch of the posterior antebrachial cutaneous nerve was shown to lie on average 7.6 mm (range 0 to 20 mm) from the portal entry and was in contact with the sheath in 43% of elbows studied.11

Mid-Anterolateral Portal

- The mid-anterolateral portal is safer and used more commonly than the distal anterolateral portal.

Field et al3 compared distal, mid, and proximal anterolateral portals and found that the more proximal portals were statistically farther from the sheath than the distal portal. They described the location of the mid-anterolateral portal as 1 cm anterior to the prominence of the lateral epicondyle and just proximal to the anterior margin of the radiocapitellar joint space.

- At 90 degrees of flexion, the radial nerve-to-sheath distance was reported to average 9.8 mm without joint distention and 10.9 mm with distention. This was more than twice the distance reported for the distal portal.
- Both inside-out and outside-in methods are effective and safe means to establish this portal. This portal is most useful for visualization of the medial elbow and débridement of the anterior radiocapitellar joint surfaces.

Proximal Anterolateral Portal

- Stothers et al11,12 described the location of the proximal anterolateral portal as 1 to 2 cm proximal to the prominence of the lateral epicondyle, with the path of the portal along the surface of the anterior humerus. The sheath is directed toward the center of the elbow joint, penetrating the brachioradialis, brachialis, and extensor carpi radialis muscles before passing through the joint capsule.

- Several studies have shown that the radial nerve-sheath distance averaged 9.9 to 14.2 mm in the 90-degree-flexed and distended elbow.3,11 This represents a statistically significant increase in the distance from the nerve from the sheath compared to either the mid or the distal portal.
- The anterior branch of the posterior antebrachial cutaneous nerve averaged 6.1 mm from the portal, with the trocar in contact with the nerve 29% of the time.11
- The proximal anterolateral portal may be made before or after the anteromedial portal, and an outside-in method is most commonly recommended.
- Although the view of the anteromedial structures was similar for all three anterolateral portals, the proximal anterolateral portal was consistently described as providing a more extensive evaluation of the joint, particularly when viewing the radiocapitellar joint.11,12,14
POSTERIOR PORTALS

- Compared with the anterior portals, all posterior portals are relatively safe\(^1\) (TECH FIG 5).
- Laterally, the posterior antebibrachial cutaneous nerve is at risk, and there are anecdotal reports of injury to the radial nerve branch to the anconal muscle.
- The ulnar nerve is the closest major nerve to any posterior portal and has been described as no closer than 15 to 25 mm from the posterior central portal.\(^1\)
  - This nerve is typically at risk only during posteromedial capsule resection for joint contracture release; however, even with safely performed perineural capsulectomy, recovery of flexion for patients with less than 110 degrees of preoperative elbow flexion still exposes the ulnar nerve to traction injury.
  - In this setting, nerve transposition is advised.
- The posterior portals may be established with the elbow between 45 and 90 degrees of flexion.\(^1,1\)
  - Less flexion is recommended and is thought to decrease the tension in the posterior tissues, expand the olecranon fossa, and provide greater access to the medial and lateral recesses.

Posterior Central Portal

- The posterior central portal, also called the straight posterior portal, has been described by many authors and is usually located 2 to 4 cm proximal to the olecranon prominence and halfway between the medial and lateral condyles.
- This is commonly the initial posterior portal and provides good visualization of the olecranon fossa, the olecranon tip, the posterior trochlea, and the medial recess. The lateral recess, the central trochlea, and the radiocapitellar joint are less well seen.
- Although the ulnar nerve-to-sheath distance is consistently described as 15 mm or more,\(^1\) the nerve should always be palpated and outlined before portal placement.
- Sharp dissection and sharp trocars are often discouraged when establishing anterior portals; however, a no. 11 blade may be used safely to create the posterior central portal and probably limits triceps tendon trauma.
- An 18-gauge needle is first used to confirm the location of the fossa, and the blade is then directed toward the center of the fossa and in line with the tendon fibers.
- For patients with arthrofibrosis, the portal may be more easily created with a sharp trocar.

Posterolateral Portal

- Andrews and Carson\(^2\) described the posterolateral portal as 3 cm proximal to the olecranon and through the lateral border of the triceps tendon.
- More distally, accessory portals may be safely placed anywhere between the proximal posterolateral portal and the soft spot.\(^1,1\) The location of the portal is determined by the intended purpose.
  - For procedures performed in the posteromedial region of the elbow, a more proximal portal will provide greater access and visualization.
  - In contrast, a more distal portal will facilitate procedures confined to the posterolateral recess.
- An 18-gauge needle is used to confirm proper access to the olecranon fossa and the lateral gutter.
- The scope is established in the olecranon fossa while remaining directly on the lateral column of the humerus to avoid capture of the posterior fat pad.
- When properly placed, this portal provides a clear view of the olecranon fossa, the olecranon tip, the posterior and central trochlea, the medial recess, the lateral recess, and the posterior radiocapitellar joint.

Direct Posterolateral Portal

- The direct posterolateral portal is typically the site used for joint inflation before anterior portal placement. The location is defined as the center of a triangle formed by the prominence of the lateral epicondyle, the prominence of the olecranon, and the radial head (see Tech Fig 1).
- Also known as the mid-lateral portal, the dorsal lateral portal, and more commonly the “soft spot” portal, this portal penetrates the anconal muscle and consistently provides the best view of the radiocapitellar joint.
**Lateral Radiocapitellar Portal**

- O’Driscoll and Morrey described the standard mid-lateral portal, also called the lateral radiocapitellar portal, and noted that this portal is difficult to create because of limited space.
- This portal is best used when a very small mechanical shaver blade may be employed in the management of OCD capitellum lesions and radiocapitellar chondral injury.
- An 18-gauge needle is used to determine appropriate portal location (TECH FIG 6).

**POSTOPERATIVE CARE**

- Wounds are routinely closed with simple sutures.
- Synovial–subcutaneous and synovial–cutaneous fistulas have been described and most commonly occur in the posterolateral portals along the lateral margin of the triceps tendon.4
  - Deep absorbable sutures placed in the fascia of the lateral triceps along with locking mattress sutures in the skin will minimize the risk for this complication.
  - Unless contraindicated by the procedure performed, the elbow is splinted near full extension to minimize swelling.
  - The arm is elevated overnight and the splint is removed the following day.
  - Passive and active range-of-motion exercises are started as soon as the procedure performed will allow.
  - For patients undergoing contracture release surgery, an axillary regional block is performed early the next day.
  - The elbow is gently taken through a full arc of motion and then placed into continuous passive motion.
  - Based on the extent of the release, the amount of swelling, and the level of pain, the patient is hospitalized for 1 to 3 days.
  - Postoperative static progressive range-of-motion braces and physical therapy are also used to recover motion.

**COMPLICATIONS**

- The incidence of neurologic complications after elbow arthroscopy has been reported to be 0% to 14%.4
  - Transient as well as incomplete and complete permanent nerve palsies, including iatrogenic nerve resection injuries, have also been described for the radial, ulnar, and median nerves.
  - Kelly et al retrospectively reviewed 473 consecutive arthroscopy procedures and found an overall complication rate of 7%.
  - Transient neuropraxia was the most common immediate minor complication and included radial nerve, ulnar nerve, posterior interosseous nerve, anterior interosseous nerve, and medial antebrachial cutaneous nerve palsies.
Risk factors include autoimmune disorder, contracture, capsulectomy, and possibly prolonged tourniquet time.

Prolonged clear or serous drainage from anterolateral and mid-lateral portal sites was the most common minor complication and was reported to occur in 5% of patients.

Deep infection occurred in 0.8% of patients; all the cases occurred in patients who had received intra-articular corticosteroids at the end of the procedure.

Mild postsurgical contracture occurred in 1.6% of patients.¹⁴

REFERENCES

DEFINITION
■ Osteochondritis dissecans (OCD) is a progressive form of osteochondrosis involving focal injury to the subchondral bone or its blood supply. It may occur in many different areas of the adolescent skeleton.
■ The knee is the most common location for OCD, but it may occur in several locations of the elbow, including the radial head, the trochlea, and the capitellum (the most common location within the elbow).
■ The injury to the subchondral bone results in loss of structural support for the overlying articular cartilage. As a result, degeneration and fragmentation of the articular cartilage and underlying bone occur, often with the formation of loose bodies.
■ The histopathology of the subchondral bone in OCD is consistent with osteonecrosis.
■ Articular cartilage injury may also occur anywhere in the elbow, especially after trauma. More common locations of nonarthritic chondral injury include the radial head and capitellum.

ANATOMY
Bony Anatomy
■ The bony anatomy of the elbow allows for two complex motions: flexion–extension and pronation–supination.
■ The ulnohumeral articulation of the elbow is almost a true hinge joint with its constant axis of rotation through the lateral epicondyle and just anterior and inferior to the medial epicondyle. This well-fitted hinge joint allows for little excessive motion or toggle.
■ The radius articulates with the proximal ulna and rounded capitellum of the distal humerus. The radiocapitellar joint and the proximal radioulnar joint allow for pronation–supination (FIG 1A). The ulnohumeral joint allows for flexion–extension of the elbow.
■ The ulnohumeral joint has 11 to 16 degrees of valgus. This results in increased compressive force in the lateral elbow (radiocapitellar joint) with axial loading.

Ligamentous Anatomy
■ The ligaments of the elbow are divided into the radial and ulnar collateral ligament complexes.
■ The lateral or radial collateral ligamentous complex provides varus stability. These ligaments are rarely stressed in the athlete.
■ The ulnar or medial collateral ligament complex consists of three ligaments: the anterior oblique, the posterior oblique, and the transverse.
■ The ulnar collateral ligament complex, particularly the anterior oblique ligament, resists valgus force, such as occurs with throwing, whereas the radiocapitellar joint is a secondary restraint to valgus force (FIG 1B).

Intraosseous Vascular Anatomy
■ There are two nutrient vessels in the lateral condyle of the developing elbow.
■ Each vessel extends into the lateral aspect of the trochlea, with one entering proximal to the articular cartilage and the other entering posterolaterally at the origin of the capsule.
■ Although these two vessels communicate with each other, they do not do so with the metaphyseal vasculature. The rapidly expanding capitellar epiphysis in the developing elbow thus receives its blood supply from one or two isolated trans-chondroepiphysyeal vessels that enter the epiphysis posteriorly.

FIG 1 • A. Cross-section of the elbow showing the round, convex capitellum and the matching concave radial head. B. Anatomy of the medial elbow ligamentous complex. The ulnar collateral ligament complex comprises three ligaments: the anterior oblique, posterior oblique, and transverse ligaments.
These vessels function as end-arteries passing through the cartilaginous epiphysis to the capitellum.

Metaphyseal vascular anastomoses do not make significant contributions to the capitellum until approximately 19 years of age, placing this region at risk for vascular injury.

PATHOGENESIS

The cause of OCD is unclear and controversial.

OCD typically affects the dominant extremity of adolescents and young adults, with onset of symptoms between 11 to 16 years of age.

Most cases are seen in high-level athletes who experience repetitive valgus stress and lateral compression across the elbow (eg, overhead throwing athletes, gymnasts, weightlifters).

The lesion usually affects only a portion of the capitellum.

Genetic factors, trauma, and ischemia have been proposed as causes.

Most authors believe that the primary mechanism of injury is repetitive microtrauma in a genetically predisposed individual’s developing elbow that results in vascular injury due to the tenuous blood supply.

The capitellum is softer than the radial head.

Repeated microtrauma, such as axial loading in the extended elbow or repeated throwing that produces valgus forces on the elbow, results in increased force in the radiocapitellar joint.

The repetitive microtrauma caused by these forces has been proposed to weaken the capitellar subchondral bone and result in fatigue fracture.

Should failure of bony repair occur, an avascular portion of bone may then undergo resorption with further weakening of the subchondral architecture. This is consistent with the characteristic rarefaction often seen at the periphery of the lesion.

The altered subchondral architecture can no longer support the overlying articular cartilage, rendering it vulnerable to shear stresses, which may lead to fragmentation.

The tenuous blood supply of the end-arterioles in the capitellum may become injured with the repetitive microtrauma, resulting in OCD.

Although a genetic predisposition to OCD has been proposed in the literature, convincing scientific evidence of OCD as a heritable condition does not currently exist. Some individuals are more susceptible than others, and this may be genetically based.

NATURAL HISTORY

The natural history of capitellar OCD is unpredictable. No reliable criteria exist for predicting which lesions will collapse with subsequent joint incongruity and which will go on to heal without further sequelae.

If healing is going to take place, it usually occurs by the time of physeal closure.

If healing is not going to take place, repetitive microtrauma and shear stresses to the articular surface of a lesion that has lost its subchondral support may result in further subchondral collapse and deformation with joint incongruity as well as articular cartilage injury, fragmentation, and loose body formation.

In advanced cases, degenerative changes accompanied by a decreased range of motion are likely to develop.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The classic patient with OCD is an adolescent athlete who experiences repetitive valgus stress and lateral compression across the elbow (eg, overhead throwing athletes, gymnasts, weightlifters).
  - The patient usually complains of the insidious onset of poorly localized, progressive lateral elbow pain in the dominant arm.
  - He or she may also note a flexion contracture.
  - The throwing athlete may note a reduction in throwing distance or velocity or both.
  - Prodromal pain is not always present.
  - Typically, pain is exacerbated with activity and relieved by rest.
  - In advanced cases in which a fragment has become unstable or loose body formation has occurred, mechanical symptoms of elbow locking, clicking, or catching may be present.

Physical examination methods

- On examination, there may be tenderness to palpation and crepitus over the radiocapitellar joint.

- Effusion indicates intra-articular irritation and may be consistent with a loose or unstable OCD lesion or loose body.

- Swelling, palpated in the posterolateral gutter (soft spot), may be appreciated.

- Crepitus may be present on range-of-motion testing.

- Loss of 10 to 20 degrees of extension is common and mild loss of flexion and forearm rotation may also be seen. Loss of pronation is less common.

- Provocative testing includes the “active radiocapitellar compression test,” which consists of forearm pronation and supination with the elbow in full extension in an attempt to reproduce symptoms.

- The examiner should rule out radiocapitellar overload as the result of ulnar collateral ligament insufficiency using the milking maneuver, modified milking maneuver, valgus stress test, or moving valgus stress test.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnostic evaluation of the elbow for OCD begins with plain radiographs—an anteroposterior (AP) view, lateral view, oblique views, and a 45-degree flexion AP, which is particularly good at revealing the lesion.

- Radiographs typically show the classic radiolucency (FIG 2A) or rarefaction of the capitellum (FIG 2B) in addition to irregularity or flattening of the articular surface.

- The lesion frequently appears as a focal rim of sclerotic bone surrounding a radiolucent crater with rarefaction located in the anterolateral aspect of the capitellum.

- Radiographs, however, may not reveal the osteochondral lesions in the earlier stages. They are not of much benefit for truly chondral lesions.

- In advanced cases, articular surface collapse, loose bodies, subchondral cysts, radial head enlargement, and osteophyte formation may be seen.

- Further diagnostic imaging of OCD lesions primarily consists of magnetic resonance imaging (MRI), although ultrasonography and bone scintigraphy have been used.

- MRI is especially valuable in assessing the integrity of the articular cartilage overlying the OCD lesion as well as in
diagnosing OCD in its early stages and identifying loose bodies (FIG 2C).

Controversy exists over the utility of contrast-enhanced MR arthrography. This technique, however, can potentially provide additional information regarding the status of the articular cartilage and identification of loose bodies.

Bone scintigraphy is very sensitive for identifying osteoblastic activity or increased vascularity at the site of an OCD lesion. However, it is nonspecific and has limited usefulness in diagnosis.

Computed tomography can help define bony anatomy and identify loose bodies.

Ultrasonography can also help in the assessment of capitellar lesions, including early stages, but ultrasound is technician dependent.

DIFFERENTIAL DIAGNOSIS

- Panner disease
- Infection
- Lateral epicondylitis
- Lateral epicondylar apophysitis
- Radial head osteochondritis dissecans
- Radial head or neck injury
- Radiocapitellar overload and chondromalacia due to ulnar collateral ligament injury
- Posterolateral rotatory instability

NONOPERATIVE MANAGEMENT

- The choice of conservative or surgical management depends on the patient’s age, symptoms, size of the lesion, and stage of the lesion, specifically the integrity of the cartilage surface.
- The goal of treatment for OCD of the elbow is to prevent the progression of the disorder, detachment of the osteochondral lesion, and degenerative changes of the articular cartilage.
- Small, nondisplaced lesions with intact overlying articular cartilage in younger (skeletally immature) athletes are best managed conservatively with relative rest and activity modification, ice, and nonsteroidal anti-inflammatory drugs, particularly if the bone scan shows increased bony activity.
- Activity modification consists of avoiding throwing activities and weight bearing on the involved arm.
- Short-term immobilization (less than 2 to 3 weeks, depending on symptoms) may be considered.
- Serial radiographs, at 10- to 12-week intervals, are obtained to monitor healing.
- Activity modification is continued until the radiographic appearance of revascularization and healing.
- Radiographic findings of OCD may persist for several years. As a result, after conservative management, the most important issue in terms of an athlete’s ability to return to sports is symptom resolution.
- Most patients can return to full activity after 6 months.

SURGICAL MANAGEMENT

- The indications for surgical treatment include persistent symptoms despite conservative management, symptomatic loose bodies, articular cartilage fracture, displacement of the osteochondral lesion, and cold bone scan.
- The surgeon must assess the size, stability, and viability of the fragment and decide whether to remove the fragment or attempt to surgically reattach it.
- Most fragments cannot be reattached and therefore are excised, followed by local débridement.
- Arthroscopic abrasion chondroplasty or subchondral drilling may be performed to encourage healing.
- Although symptoms usually improve, about half of all patients will continue to have chronic pain or limited range of motion.
- In general, many athletes cannot return to their prior levels of competition.
- Surgical indications for operative management of stable lesions with intact articular cartilage include radiographic evidence of lesion progression and failure of symptom resolution despite a 6-month trial of a conservative, nonoperative regimen.
Arthroscopic examination, débridement as needed, and drilling or microfracture of the OCD lesion (with or without in situ pinning) are usually the surgical treatments of choice.

Unstable lesions, characterized by overlying articular cartilage injury and instability as well as collapse or disruption of the subchondral bone architecture, and those with loose bodies are usually managed surgically.

These lesions are frequently flap lesions. They characteristically present with more advanced radiographic changes (including a well-demarcated fragment surrounded by a sclerotic margin).

There is controversy as to whether simple fragment excision or reduction (open or arthroscopic) and internal fixation is the preferred treatment. Many authors advocate excision of displaced fragments, often augmented by drilling or microfracture.

Critical considerations in operative planning include the size and integrity (viability) of the fragment, the subchondral architecture on the fragment and the opposing bony bed, the potential for anatomic restoration of the articular surface, and the method of fixation if attempted.

Internal fixation of the fragment may be performed using metallic screws, bioabsorbable screws or pins, Kirschner wire, bone pegs, and dynamic staple fixation.

There have been a few reports of osteoarticular autograft or allograft plugs in the treatment of more advanced lesions, but experience with this method is limited. The current recommendations are for lesions that involve the lateral column.

Preoperative Planning

Before surgery, an MRI, preferably with contrast, can be used to assess the integrity of the articular cartilage to help determine whether débridement, loose body removal, and drilling may be needed or more advanced techniques, such as reduction and internal fixation or osteochondral transfer, may be needed.

The MRI of the joint is also inspected for loose bodies—their number and location (anterior vs. posterior elbow) (see Fig 2C).

FIG 3 • A. Lateral positioning for elbow arthroscopy, including tourniquet placement. B. Setup in the operating room for the lateral position. C. Prone position of the patient. This is the preferred position, particularly due to the ease of posterior elbow access. The setup of the room is the same and the relative position of the elbow for the surgeon is similar between the prone and lateral positions. D. Supine position of the patient. Some surgeons prefer this position because it is easier to convert to open surgery and easier anesthesia management; however, posterior arthroscopic access is more difficult in this position.
All imaging studies are reviewed.
Examination under anesthesia is performed to assess range of motion and ligamentous stability, particularly valgus laxity, as injury to the ulnar collateral ligament in the athlete may increase the load on the radiocapitellar joint.

**Positioning**
- Elbow arthroscopy can be performed in the supine, lateral, or prone position (FIG 3).
- Prone positioning is preferred because it allows easy access to the elbow, reduces the risk of sterility breaks if the arm needs to be in a finger-trap device, as needed for supine elbow arthroscopy, and arthroscopy.
- The patient is positioned on chest rolls and padding under the knees and feet and ankles.
- The arm is placed on an arm holder.

- A sterile tourniquet is placed after the arm is prepared and draped.

**Approach**
- All cases are approached in the same manner initially.
  - Diagnostic arthroscopy of the elbow is carried out, using a proximal anteromedial portal, a proximal anterolateral portal, and two posterior portals. This allows for assessment of the entire joint to ensure that loose bodies are not missed.
  - The capitellum may be seen from the proximal anteromedial portal (FIG 4A) while the elbow is taken through a full range of motion.
  - A direct lateral portal (sometimes called the soft spot portal) is then used to allow direct access to the radiocapitellar joint and is needed to confirm the extent of the OCD or chondral lesion (FIG 4B).

**ARTHROSCOPIC DÉBRIDEMENT AND LOOSE BODY REMOVAL**
- Elbow arthroscopy is begun in the prone (my preference), lateral, or supine position, using the proximal medial portal to visualize the capitellum.
- Complete elbow examination is mandatory to look for loose bodies:
  - Proximal anteromedial portal
  - Proximal anterolateral portal
  - Posterior central portal
  - Postrolateral portal
  - Direct lateral portal
- Loose bodies tend to hide:
  - In the proximal radioulnar joint anteriorly or the gutters
  - In the olecranon fossa or gutters posteriorly, particularly the lateral gutter
- When looking at the capitellum from the proximal anteromedial portal, instrumentation (shavers, burrs, graspers, and curettes) may be accomplished using the proximal anterolateral portal.
  - Flexion and extension of the elbow allow for enhanced visualization of the capitellum.
- Loose bodies and chondral fragments may be removed via the anterior portals (TECH FIG 1A,B).
- Then the arthroscope is brought in from the posterior portals to look for loose bodies.
The direct lateral (“soft spot”) portal is used for complete evaluation of the capitellum.

This portal is mandatory to fully evaluate the extent of the lesion and to allow for adequate débridement of loose cartilage.

Often loose bodies will be found using this portal. Débridement is performed using shavers, curettes, graspers, and rongeurs to remove loose bodies and any loose, scaly, or fragmented cartilage (TECH FIG 1C).

The direct lateral (“soft spot”) portal is used for complete evaluation of the capitellum.

This portal is mandatory to fully evaluate the extent of the lesion and to allow for adequate débridement of loose cartilage and may allow for a good direction for microfracturing the bed.

Abrasión is carried out from either anterolateral or direct lateral portals to the complete lesion. This may be done with a shaver on high speed or burr.

For chondral lesions, abrasión arthroplasty involves removal of the zone of calcified cartilage, then use of a burr to lightly remove only a partial thickness of the subchondral bone to expose subchondral arterioles to bring blood into the lesion. The key is not to go too deep into the cancellous bone.

For OCD with a cartilage cap that is not intact, abrasion is done lightly to remove only a little bone to allow bleeding into the bony bed.

Microfracture or drilling can also be used to bring blood into the defect when the OCD or chondral lesion results in an exposed bony bed, with the theoretical benefit of microfracturing being that less bone is lost and there is no heat production, which may be seen with drilling.

The bone is pierced every 3 to 4 mm for a 4-mm depth with an awl for microfracture or 0.062 Kirschner wire for drilling (TECH FIG 2).

If the anterolateral or direct lateral portals do not allow for adequate directionality of the drilling or microfracture, an additional outside-in portal may be made based on the known anatomy and using a spinal needle.
**DRILLING FOR INTACT OCD LESIONS**

- When the OCD lesion has an intact overlying chondral surface, then drilling may enhance or stimulate a healing response of the lesion, although this is not frequently needed.
- The key is to try to prevent violation of the OCD cartilage cap, although some surgeons drill from outside-in trying to avoid injury to the articular cartilage and some drill from the joint, which will perforate the articular cartilage.
- Elbow arthroscopy is begun in the prone (my preference), lateral, or supine position, using the proximal medial portal to visualize the capitellum.
  - Complete elbow examination using all four standard portals and the additional direct lateral arthroscopic portals is mandatory to look for loose bodies.
- When looking at the capitellum from the proximal anteromedial portal, instrumentation (shavers, burrs, graspers, and curettes) may be done using the proximal anterolateral portal.
- Flexion and extension of the elbow allow for enhanced visualization of the capitellum.
- Next, the arthroscope is brought in from the posterior portals to look for loose bodies.
- The direct lateral (“soft spot”) portal is then used for complete evaluation of the capitellum.
- OCD lesions with intact articular cartilage, subchondral softening, fibrillated cartilage, or cartilage character change may be identified visually or palpably using a probe (TECH FIG 3) or alternatively using fluoroscopic imaging.
- Drilling through the cartilage and through the sclerotic subchondral bone is done in an effort to promote healing.
- Attempts are made to limit the number of perforations through the intact cartilage, but the subchondral plate should be penetrated multiple times.
- This may be accomplished by redirecting the drill in different directions from the same single (or a few) perforations through the articular cartilage.
- The lesion is pierced with an 0.062 Kirschner wire for drilling.
- If the anterolateral or direct lateral portals do not allow for adequate directionality of the drilling, an additional outside-in portal may be made based on the known anatomy and using a spinal needle.
DRILLING FOR INTACT OCD LESION: OUTSIDE-IN TECHNIQUE

- When the OCD lesion has an intact overlying chondral surface then drilling may enhance or stimulate a healing response of the lesion.
- The key is to try to prevent violation of the OCD cartilage cap, although some surgeons drill from outside in trying to avoid injury to the articular cartilage and some drill from the joint, which will perforate the articular cartilage.
- Elbow arthroscopy is begun in the prone (my preference), lateral, or supine position, using the proximal medial portal to visualize the capitellum.
  - Complete elbow examination using all four standard and the additional direct lateral arthroscopic portals is mandatory to look for loose bodies.
- When looking at the capitellum from the proximal anteromedial portal, instrumentation (shavers, burrs, graspers, and curettes) may be done using the proximal anterolateral portal.
  - Flexion and extension of the elbow allow for enhanced visualization of the capitellum.
- Next, the arthroscope is brought in from the posterior portals to look for loose bodies.
  - The direct lateral (“soft spot”) portal is then used for complete evaluation of the capitellum.
- OCD lesions with intact articular cartilage, subchondral softening, fibrillation of the cartilage, or cartilage character change may be identified visually or palpably (see Tech Fig 3) or alternatively using fluoroscopy.
- Fluoroscopy is then brought in to identify the lesion.
- Using an anterior cruciate ligament tibial guide or posterior cruciate ligament femoral guide can be useful to help aim the drill bit from outside the elbow toward the lesion.
- Depending on the location of the lesion, the drill is brought from proximal and slightly anterior to the lateral epicondyle or posteriorly on the distal humerus.
- A small incision is made at the proposed drilling entry site and blunt dissection is done to bone.
- The lesion is drilled with a 0.062 Kirschner wire for drilling while watching with fluoroscopy or arthroscopy to ensure the articular cartilage is not violated.
- Multiple passes with the Kirschner wire should be performed to enhance healing throughout the lesion.

INTERNAL FIXATION

- When the OCD fragment is partially detached or completely detached but not malformed and there is significant bone on the cartilage fragment, consideration for reattachment is recommended.
- The principle is to stimulate healing and to stabilize the fragment within the bony bed.
- Elbow arthroscopy is begun in the prone, lateral, or supine position, using the proximal medial portal to visualize the capitellum.
- If it is likely the patient will need internal fixation of a partially detached OCD fragment, and there is a possibility that an arthrotonomy is needed, I have found performing the surgery in the lateral position is a bit easier.
- Complete elbow examination using all four standard and the additional direct lateral arthroscopic portals is mandatory to look for loose bodies.
- When looking at the capitellum from the proximal anteromedial portal, instrumentation (shavers, burrs, graspers, and curettes) may be done using the proximal anterolateral portal.
  - Flexion and extension of the elbow allow for enhanced visualization of the capitellum.
- All underlying bone is débrided with an arthroscopic shaver or burr or manually with curettes or pituitary rongeurs.
- Next, the arthroscope is brought in from the posterior portals to look for loose bodies.
  - The direct lateral (“soft spot”) portal is used for complete evaluation of the capitellum.
  - This portal is mandatory to fully evaluate the extent of the lesion and to allow for adequate débridement and preparation of the bed.
- The osteochondral flap or undersurface of the fragment is elevated and the underlying sclerotic bone is curetted and débrided of fibrous tissue (TECH FIG 4A). Drilling of the base is also performed to stimulate healing.
- The abrasion and drilling are carried out from either anterolateral or direct lateral portals to the complete lesion. This may be done with a curette, a shaver on high speed, or a burr and a drill or Kirschner wire to gently débride the bed without removing much bone.
- The flap is then replaced within the bed.
- Retrograde pinning of the lesion with threaded or unthreaded wires can be performed with the wires exiting the lateral epicondyle for later removal (TECH FIG 4B,C).
  - The ends of the pins should be positioned below the articular surface so that the wires do not penetrate the joint space.
  - Bioabsorbable pins and bioabsorbable screws have been used as an alternative (TECH FIG 4D).
- Further, some surgeons will place metallic screws for fixation. These can either be headless variable-pitched screws that are buried beneath the articular surface, or regular-headed screws, which some prefer for better compression but must be removed.
- If the anterolateral or direct lateral portals do not allow for adequate directionality of the drilling or microfracture, an additional outside-in portal may be made based on the known anatomy and using a spinal needle.
- An arthrotomy may be necessary to perform the débride-ment or internal fixation.
When the OCD fragment is loose and it is not possible to fix the lesion back to the bony bed, and there is a large crater, particularly if it involves the lateral column, then consideration is given to inserting osteochondral auto-graft plugs into the defect to eliminate or reduce edge loading and loss of lateral support for the joint.

This is achieved by taking osteochondral plugs from the knee and implanting them into the capitellum.

Elbow arthroscopy is begun in the prone, lateral, or supine position, using the proximal medial portal to visualize the capitellum. Because insertion of the plugs often requires an arthrotomy and the grafts must come from the knee, the supine position is preferred.

Complete elbow examination using all four standard and the additional direct lateral arthroscopic portals is mandatory to look for loose bodies.

When looking at the capitellum from the proximal anteromedial portal, instrumentation (shavers, burrs, graspers, and curettes) may be done using the proximal anterolateral portal.

Flexion and extension of the elbow allow for enhanced visualization of the capitellum.

A posterior or posterolateral approach may be used.

The radiocapitellar joint is approached anteriorly by splitting the intermuscular plane between the extensor digitorum communis and the extensor carpi radialis longus and brevis, exposing the anterior capsule, which is then incised.

The posterior approach uses a posterior longitudinal skin incision with the elbow in full flexion. Then the anconeus and posterior capsule are divided, providing direct access to the OCD lesion.

The posterolateral Kocher approach uses the interval between the anconeus and extensor carpi ulnaris. The lateral collateral ligament complex is protected and preserved, allowing exposure of the posterior radiocapitellar joint.

A commercially available osteochondral graft harvesting system is used.

The size of the lesion is assessed to decide how many grafts and of which size are necessary, although usually less than 100% fill is achieved.

Recipient sockets are created in the lesion with the recipient graft harvesting tool.

Occasionally the sclerotic bed makes it difficult to use the recipient harvesting tool and a cannulated drill is needed to make the recipient bed.

Drilling is carried out at the base of the socket before inserting the graft to allow for marrow stimulation and enhance healing potential.

Osteochondral grafts about 10 mm long are then harvested arthroscopically or with mini-arthrotomy from the knee intercondylar notch or periphery of the non-weight-bearing portion of the lateral femoral condyle.

There are only a few case reports of this technique. Some use multiple 3.5-mm plugs and some use single larger osteochondral plugs.

The depth of the recipient socket is measured with a calibrated depth gauge or alignment stick.

The length of the osteochondral autograft plug is matched to the depth of the recipient socket.

The graft is seated flush with the surrounding intact cartilage.

Complete coverage of the lesion usually is not possible, though coverage of 80% to 90% of the lesion size should be achieved.
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Nerve injury</th>
<th>The greatest risk of elbow arthroscopy, for osteochondritis dissecans or any other diagnosis, is nerve injury. Knowledge of elbow neuroanatomy, particularly as it relates to the arthroscopic portals, is of paramount importance. It is safest to use the proximal medial portal and the proximal lateral portals anteriorly. Distending the joint, using the outside-in technique, and using blunt instruments after skin incision only all help to reduce iatrogenic nerve injury.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Direct lateral portal</td>
<td>Familiarity with the direct lateral portal is critical for the evaluation and treatment of chondral and osteochondral lesions of the capitellum. The posterior radial head and capitellum are best seen with this portal, and loose bodies from osteochondritis dissecans occasionally may only be seen from this portal. Full appreciation of the lesion cannot be made without the use of this portal.</td>
</tr>
<tr>
<td>Converting to an open procedure</td>
<td>Occasionally synovitis or lack of working space makes visualization of the lesion difficult. Further, fixation of the lesion may be difficult arthroscopically. If visualization or fixation is difficult arthroscopically, there should be a low threshold to converting the procedure to open. The threshold of conversion to open should be based on experience and comfort with arthroscopy.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- After elbow arthroscopy for débridement or loose body removal:
  - Early range-of-motion exercises are encouraged to prevent loss of elbow motion. Other early goals include reducing swelling, pain, and muscular atrophy.
  - As motion becomes full and the soft tissues are healing with minimal swelling, rehabilitation concentrates on strengthening and endurance of the joint as well as normalization of arthrokinematics of the elbow. This usually begins after 2 weeks.
  - After 4 weeks, the athlete is prepared to return to functional activities with more strengthening, endurance, and flexibility. However, some believe that individuals with OCD lesions who have a defect should not return to sports activities because of the risk of arthritic change in the elbow.
  - After in situ drilling, return to sports is usually delayed until 3 to 6 months postoperatively, when there is good radiographic evidence of bony incorporation and healing.
  - After microfracture or internal fixation:
    - Range of motion is encouraged, but some clinicians put their patients in a range-of-motion brace positioned in varus to reduce stress over the radiocapitellar joint.
    - Some also consider adding the use of continuous passive motion to help in cartilage nourishment to encourage the microfracture clot or the healing surface of a fixed lesion to reduce adhesions. In these scenarios, strengthening is usually not initiated for at least 6 weeks.
    - Return to gymnastics or throwing sports is delayed until 6 months postoperatively.
  - Following the autograft transfer procedure:
    - The joint is immobilized until 2 weeks postoperatively, when the cast or splint is discontinued.
    - Beginning week 3, range-of-motion exercises are started.
    - Strengthening of the elbow and forearm is begun at 3 months postoperatively, and a throwing program is initiated at 6 months, with full return to participation at 10 to 12 months postoperatively.

OUTCOMES

- Reports in the literature on follow-up of the conservative and surgical management of OCD are difficult to compare and interpret because there is a lack of a universally accepted classification system, the numbers of patients in most series is limited, and there are disparities in age at presentation, symptoms, lesion size, location, stability, and viability. Further, there are differences in the method of diagnostic imaging used, surgical technique, and length of follow-up.
  - A consensus exists in the literature on the need to limit continual high-stress loading of the radiocapitellar joint in patients treated (even successfully) with OCD to prevent the deterioration of the frequently obtained short-term favorable results. As a result, most pitchers are counseled to move to other positions and gymnasts are advised of the difficulty in returning to continued high-level competitive gymnastics.
  - Conservative treatment of OCD does not provide uniformly successful results.
  - Takahara et al6,7 presented the results of nonoperative management of early OCD lesions with an average follow-up of 5.2 years and reported that more than half of these patients had pain with activities, and fewer than half of the lesions showed radiographic improvement.
  - Surgery also does not result in uniformly good outcomes.
  - In one of the longest follow-up studies available in the elbow OCD literature, Bauer et al1 presented the results of 31 patients (23 of whom were treated surgically with lesion or loose body excision) with capitellar OCD followed for an average of 23 years. At follow-up, the most common complaints were decreased range of motion (average 9 degrees of flexion loss, 2 degrees of extension loss, and 6 degrees of pronation–supination loss) and pain with activity. Radiographic evidence of degenerative changes involving the elbow joint was present in 61% and radiolunate enlargement in 58%.
  - McManama et al4 presented data on 14 adolescents with radiocapitellar OCD lesions treated with excision via a lateral arthrotomy with average follow-up of 2 years. Lesions were not sized, but 93% had good or excellent results.
  - Jackson et al13 reported on the roughly 3-year follow-up of OCD lesions in 10 female gymnasts treated primarily with curettage of loose cartilage, drilling, and loose body excision. All of the patients reported symptomatic relief, but only one patient returned to competition, and she did so with discomfort. Average loss of extension at follow-up in this series was 9 degrees, which is consistent with other reports.
  - Ruch et al2 presented the follow-up at an average of 3.2 years after arthroscopic débridement alone for management of elbow
OCD in 12 adolescents. The average flexion contracture improved 13 degrees (23 degrees preoperatively to 10 degrees postoperatively). All patients had capitellar remodeling on follow-up radiographs, and approximately 42% had associated radial head enlargement. Ninety-two percent of the patients in this series were highly satisfied, with minimal symptoms. Of note, five patients (42%) had a triangular lateral capsular avulsion fragment (seen radiographically but not at arthroscopy), which had a statistically significant association with a worse subjective outcome.

Baumgarten et al\(^2\) presented an average 4-year follow-up (range 24 to 75 months) on 17 elbows with OCD treated in 16 patients. Their results showed that the average flexion contracture improved 14 degrees, approximately 24% had pain, seven of nine (78%) throwers and four of five (80%) gymnasts were able to return to sport, and no patient had demonstrable degenerative joint disease.

**COMPLICATIONS**

- The complications seen with OCD treated surgically or not include flexion contracture, elbow pain, arthritis, and inability to return to sports.
- Loose bodies may develop in elbows treated nonoperatively.

Surgical intervention, particularly arthroscopy, has the added risk of nerve injury because the neural structures are so close to the usual elbow arthroscopy portals.

**REFERENCES**

DEFINITION

- Valgus extension overload of the elbow is commonly seen in the overhead throwing athlete and is associated with medial compartment distraction, lateral compartment compression, and posterior compartment impingement.4,6

ANATOMY

- The bony articulation of the elbow joint provides primary stability to varus and valgus force at angles of less than 20 degrees and greater than 120 degrees of flexion.
- Soft tissues are the chief stabilizers between 20 and 120 degrees, where most athletic activity occurs.
- The ulnar collateral ligament (UCL) is the primary restraint to valgus stress.
- It is composed of the anterior band, the posterior band, and the transverse ligament.
- The anterior band is further divided into anterior and posterior bundle, which perform reciprocal functions (FIG 1).
- UCL insufficiency can be subtle, with ligament-sectioning studies showing a 3-degree difference when the anterior band of the UCL is cut.2

PATHOGENESIS

- Valgus extension overload typically occurs in repetitive overhead athletes, most commonly with pitchers. The repetitive pitching motion imparts a large valgus force on the elbow.

Resulting microtrauma and incomplete recovery can lead to attenuation of the UCL.
- Failure of the UCL leads to abnormal valgus rotation of the elbow, affecting the mechanics of the highly constrained articulation of the posterior elbow joint.
- This leads to bony impingement of the posteromedial olecranon and its corresponding fossa.
- Chronic bony impingement can lead to chondral lesions as well as reactive osteophyte formation of the posterior compartment (FIG 2).

NATURAL HISTORY

- Thus far, no studies have been performed documenting the natural history of the disease process.
- It is postulated that chronic impingement and valgus extension overload can lead to posteromedial olecranon osteophyte formation that can cause ulnar nerve irritation and loss of elbow extension as well as posterior compartment elbow arthritis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient typically complains of loss of extension with posterior or posteromedial elbow pain.
- Pitchers will report pain during the acceleration and follow-through phases of the throwing motion (FIG 3).
Physical examination maneuvers relevant to valgus extension overload include:

- Valgus extension overload test: This maneuver acts to simulate impingement occurring with the throwing motion and to reproduce the symptoms of posterior elbow pain.
- Valgus stress test: Increased medial joint space opening, loss of end point, or pain elicited is significant for UCL insufficiency.
- Milking maneuver: Maneuver eliciting pain, apprehension, or instability indicates UCL insufficiency.
- Posterior olecranon impingement
- Range of motion of elbow: may reveal loose bodies, chondromalacia, or osteophyte formation; flexion contracture may signify either osteophyte impingement or anterior capsular contracture
- Examination of the elbow should also evaluate for other causes of medial-sided elbow problems, such as isolated UCL insufficiency, ulnar neuropathy, medial epicondylitis, and flexor pronator rupture.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs frequently reveal a posterior olecranon osteophyte on standard lateral or anteroposterior views (FIG 4A).
- Some authors also advocate an olecranon axial view (FIG 4B).
- Because radiographs cannot predict chondral lesions and soft tissue injuries and often underestimate loose body formation, magnetic resonance (MRI) and computed tomography are frequently used.
- MRI can also be important in investigating a potential UCL tear (FIG 4C).

**DIFFERENTIAL DIAGNOSIS**

- Isolated UCL insufficiency
- Medial epicondylitis
- Flexor–pronator rupture
- Ulnar neuropathy

**NONOPERATIVE MANAGEMENT**

- Before recommending surgery, the physician should usually treat the patient nonoperatively for 3 to 6 months.
- Specific goals to be attained during this time are full, nonpainful range of motion; absence of pain and tenderness on physical examination; and satisfactory muscle strength, power, and endurance.
- The patient begins treatment with an initial period of rest (1 to 3 weeks), allowing any synovitis and inflammation to resolve.
- Next, he or she begins wrist and elbow flexor and extensor muscle stretching and strengthening exercises.
- Finally, an interval-throwing program is instituted.

**FIG 3** The pitching athlete with valgus extension overload will often complain of pain during the acceleration and follow-through phases of throwing.

**FIG 4** AP (A) and olecranon axial (B) radiographs showing spur formation along the posteromedial olecranon. C. Coronal section of MRI demonstrating injury to the ulnar collateral ligament.
SURGICAL MANAGEMENT

- Relative contraindications to elbow arthroscopy include severe bony or fibrous ankylosis and previous surgery that has distorted the native anatomy, such as a previous ulnar nerve transposition.

Preoperative Planning

- A thorough history is paramount to planning for arthroscopic elbow surgery.
- The surgeon should confirm that the ulnar nerve is indeed in the groove and cannot be subluxated.
- The surgeon must assess for valgus instability when considering valgus extension overload.
- Failure to address UCL instability in the setting of valgus extension overload may lead to treatment failure.

Positioning

- We prefer the prone position for all elbow arthroscopy because it allows for the elbow to be stabilized as well as giving improved access to the posterior compartment. Posteromedial olecranon spur excision is especially facilitated by the prone position.
- We routinely use a pneumatic tourniquet and a prone arm holder.
- The elbow should be positioned and draped so that the arm is supported by the holder at the proximal upper arm, the elbow rests at 90 degrees of flexion, and the antecubital fossa is free from contact with the holder (FIG 5).

Approach

- Elbow arthroscopy has made open resection of olecranon osteophytes primarily a point of historic interest. However, occasions still exist when an open procedure should be performed.
- The determining factor in the decision-making process is whether a contraindication to elbow arthroscopy is present.
- A posteromedial approach to the elbow is used when concomitant UCL reconstruction, ulnar nerve transposition, or exploration of a previously transposed ulnar nerve is to be accomplished in conjunction with removal of posteromedial osteophytes.

FIG 5 • Intraoperative photograph showing prone positioning for elbow arthroscopy.

Equipment

- General anesthesia is preferred because use of regional anesthesia makes the immediate postoperative motor and sensory examination difficult to interpret.
- A standard 4.0-mm arthroscope, power inflow or pump, standard power débrider, and abraders are required.
- Hand-held instruments as well as only blunt trocars should be used.
- The video monitor is placed on the opposite side of the patient.

Examination Under Anesthesia

- Examination under anesthesia is essential to develop a feel for the character and cause of any extension block.
- A bony block has a hard, sudden stop and a feeling of bony impingement. Anterior capsular contracture often has a slightly softer feel at terminal extension.
- Valgus instability testing throughout the range of motion helps to assess the status of the UCL.

DIAGNOSTIC ARTHROSCOPY

- The medial epicondyle, lateral epicondyle, and ulnar nerve are outlined.
- The surgeon confirms that the ulnar nerve is indeed located within the groove and remains so with range of motion of the elbow.
- The lateral “soft spot” portal location is identified and 20 cc of saline is injected into the elbow joint. Often a slight elbow extension will be seen as the capsule is insufflated.
- Diagnostic arthroscopy must include a complete inspection and evaluation of the elbow.
- An arthroscopic valgus instability test should be performed and medial stability should be documented (TECH FIG 1A,B).
- The posterior compartment should be thoroughly evaluated.
- Examination of the olecranon–olecranon fossa articulation may show osteophyte formation of the posteromedial olecranon (TECH FIG 1C,D).
- The olecranon fossa of the humerus should be evaluated for hypertrophy, chondromalacia, and spur formation.
- A systematic examination of the entire elbow joint is necessary to identify and remove any loose bodies present.
Chapter 20  ARTHROSCOPIC TREATMENT OF VALGUS EXTENSION OVERLOAD

TECH FIG 1 • A. The arthroscopic valgus instability test is performed to assess for significant opening in the ulnohumeral articulation. B. A diastasis in the medial ulnohumeral articulation is noted. C,D. Arthroscopic views of a posteromedial bone spur.

POSTEROMEDIAL OLECRANON SPUR REMOVAL

- First, a viewing portal is established through a posterolateral portal.
- A direct posterior or triceps-splitting portal is established for access of the motorized resector or burr. The posteromedial spur is then resected (TECH FIG 2A,B).
- The ulnar nerve has a close relationship to the medial olecranon. While working medially, the surgeon should minimize the use of suction, use a hooded burr, and always keep the hooded portion oriented toward the ulnar nerve (TECH FIG 2C).

EVALUATION AND TREATMENT OF ARTICULAR CARTILAGE

- After clearing out the olecranon fossa, the articular cartilage is carefully inspected.
- Areas of chondromalacia can be treated by the surgeon’s choice of microfracture, abrasion chondroplasty, or benign neglect.

TECH FIG 2 • A,B. Posterior compartment olecranon spur excision. C. Use of a hooded burr for posteromedial spur resection. The instrument is always pointed away from the ulnar nerve.
DEEPENING OF OLECRANON FOSSA

- Occasionally, hypertrophy of the olecranon fossa necessitates a deepening or fenestration of the olecranon fossa (TECH FIG 3).
- This can be performed using the same instruments and positioning.
- When resection is complete, the surgeon should assess elbow extension and valgus instability with a repeat arthroscopic valgus instability test.

TECH FIG 3 • Arthroscopic views both during (A) and after (B) olecranon fossa fenestration.

POSTOPERATIVE CARE

- Patients with valgus extension overload undergoing isolated spur excision are moved rapidly through the rehabilitation process.5
- A sling is used sparingly for comfort for the first 7 to 10 days.
- After the first week, patients are encouraged to use the elbow normally for activities of daily living, and they can begin strengthening and range-of-motion exercises.
- We include flexor–pronator mass strengthening to improve dynamic valgus instability.
- When patients reach a pain-free plateau, they can be advanced through an interval-throwing program.
- This throwing program typically begins at 6 weeks.
- A target return to competitive pitching is 3 to 4 months.

OUTCOMES

- The study by Wilson et al6 included five patients treated with open biplanar spur excision. One reoperation was required in a patient with severe chondromalacia of the olecranon articular surface.
- Bartz et al1 reported on a series of 24 baseball pitchers treated with a mini-open technique. Nineteen of the 24 obtained complete relief and were able to equal or exceed their preoperative throwing velocity. However, two patients did require reoperation for UCL reconstruction.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Thorough preoperative history and physical examination</th>
<th>Screening for contraindications to elbow arthroscopy can prevent iatrogenic nerve injury. The surgeon should not create a medial portal if the location or orientation of the ulnar nerve is unclear.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arthroscopic valgus instability test</td>
<td>A careful test before and after spur excision helps prevent unrecognized ulnar collateral ligament instability.</td>
</tr>
<tr>
<td>Use of hooded motorized resector</td>
<td>Motorized shavers, even when used properly, present a significant risk of injury to the ulnar nerve.</td>
</tr>
</tbody>
</table>

COMPLICATIONS

- Thus far, no complications of this diagnosis or procedure have been documented.
- Use of a motorized shaver in the medial gutter to débride olecranon osteophytes in close proximity to the ulnar nerve does warrant extreme caution.
- In addition, an unrecognized UCL insufficiency has been a documented cause of reoperation.
- Often this diagnosis is difficult to make in the immediate postoperative period; it may become apparent only when the athlete cannot regain his or her pitching velocity and control.

REFERENCES

**DEFINITION**

- Elbow stiffness can cause significant impairment in function of the upper extremity, especially in performance of the activities of daily living (ADLs).
- A lack of compensatory biomechanical function (ie, the scapula for the shoulder) makes elbow stiffness poorly tolerated.
- A functional arc of 100 degrees (30 to 130 degrees) is required for most ADLs. ¹³
- Posttraumatic elbow motion loss is most common, but osteoarthritis, inflammatory conditions, systemic conditions (head injury), and neurologic problems may also cause contractures.
- Flexion loss is less tolerated than extension loss, but loss of extension is more common. ¹²
- The key to treatment is to determine the functional and occupational impairment and not base treatment decisions solely on the absolute loss of motion of the elbow. ⁷

**ANATOMY**

- The elbow has a predilection for stiffness based on its anatomy: the close relationship of the capsule to the surrounding ligaments and muscles and the presence of three joints within a synovial-lined joint cavity—a hinge (ginglymus) ulnohumeral articulation and rotatory joint (trochoid) of both the radiohumeral and radioulnar joints. ⁷
- The anterior elbow capsule proximally attaches above the coronoid fossa and distally extends to the coronoid (medial) and the annular ligament (lateral). The posterior capsule starts proximally just above the olecranon fossa and inserts at the articular margin of the sigmoid notch and annular ligament (FIG 1).
- The anterior capsule is taut in extension and lax in flexion, with the strength of the capsule provided from the cruciate orientation of the fibers of the anterior capsule.
- Greatest capsular capacity is at 80 degrees flexion. ⁵,¹⁵
  Normal capacity of 25 mL is reduced significantly in a contracture state to 6 mL. ⁵,¹⁵

---

**FIG 1** - Anatomic drawing of elbow capsular structures. The anterior (A) and posterior capsular areas (B) are highlighted. The anterior capsule distally extends to the coronoid medially and annular ligament laterally. C. Lateral diagram of the elbow shows the capsular size and fat pad.
There is loss of joint volume (20 mL to 6 mL) and thickened capsular width (from a normal width of approximately 2 mm). Posttraumatic contractures thicken and tighten variable areas of the elbow capsule, especially the anterior aspect.

**NATURAL HISTORY**

Elbow contracture is frequently posttraumatic. Heterotopic ossification may occur in conjunction with capsular thickening. Patients most at risk are those with combined head and elbow trauma, burn patients, and those who have undergone surgical approaches to the elbow. Classification of the cause of elbow stiffness is important in making treatment decisions (Table 1). Most contractures have mixed elements (both intrinsic and extrinsic factors). Morrey characterized elbow stiffness as static or dynamic, based on tissue involvement (Table 2).

**PATIENT HISTORY AND PHYSICAL FINDINGS**

It is critical to determine the degree of functional impairment for each patient. Management decisions should be based on subjective impairment, not necessarily the amount of motion loss. The surgeon should obtain a history of associated conditions because neurologic, peripheral nerve, or brain injury may influence management decisions.
The surgeon should assess the function of the entire ipsilateral and contralateral upper extremity. The surgeon should determine hand dominance, the patient’s occupation, and the extent of prior therapy, including bracing (both static and dynamic). Physical examination should start with the head, including the cranial and cervical nerves. The surgeon palpates the cervical spine and checks the spine range of motion. The surgeon evaluates the shoulder joint to ensure good strength and range of motion. Careful assessment of the ulnar nerve.

Two-point discrimination: A normal amount of discrimination is less than 6 mm. Froment sign and intrinsic hand muscle function: The patient is asked to grasp a piece of paper between the abducted thumb and index finger. The patient must keep his or her thumb flat against the index finger. If the patient cannot do so, the flexor pollicis longus contributes more to hold paper and indicates weakness of the adductor pollicis and ulnar nerve injury. Decreased grip strength may signify an ulnar nerve problem. Elbow range of motion: Flexion and extension with the humerus flexed to 90 degrees, pronation, and supination can be objectively evaluated with a linear object (pencil) held in a clenched fist and the elbow at the side of the body.

Elbow instability examination: The surgeon should check the ligamentous restraints to varus and valgus stress. Ligaments are assessed with varus and valgus stress at 0 and 30 degrees of flexion if amenable. The cubital tunnel is palpated to assess for tenderness or a positive Tinel’s sign.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs (anteroposterior [AP] and lateral) are usually adequate.
- The AP provides joint line and subchondral bone visualization.
- If an elbow is contracted more than 45 degrees, the AP view of the joint line is usually distorted, but advanced imaging is rarely necessary unless a fracture or malunion is present.
- The lateral view may show osteophytes on the olecranon or coronoid (FIG 3A, B).
- If there is articular incongruity or other joint abnormalities, the surgeon should consider obtaining a computed tomography scan with reformatted images in the coronal and sagittal planes.
- Radiographs can be used to follow the maturation process of heterotopic ossification.
- Arthroscopic treatment is usually not recommended in the presence of heterotopic ossification, which usually signifies multiple extrinsic causes of elbow contracture, not amenable to arthroscopic treatment (FIG 3C).

**DIFFERENTIAL DIAGNOSIS**
- Heterotopic ossification
- Closed head injury
- Burns
- Elbow fracture–dislocation
- Dysplastic radial head (congenital)
- Muscular hypotonia
- Stroke

**NONOPERATIVE MANAGEMENT**
- Nonoperative management should be considered up to 6 months after contracture onset. Response is better if there is a soft “spongy” endpoint during range of motion.
- The goal is to gain motion gradually without causing additional trauma to the capsule and subsequently development of additional capsular contracture (more pain, inflammation, and swelling leads to more contracture).

</tr>
</tbody>
</table>

Edema control is critical, and therapy should focus on this, not exercises that induce inflammation around the elbow. Static and preferably patient-adjusted static progressive splints (turnbuckle splints) have proven valuable and should be used between therapy sessions. Dynamic splinting may be helpful, but care should be taken not to incite an inflammatory process because these provide a constant tension over time. Static progressive splints that allow for stress relaxation of the soft tissues are more effective and better tolerated.

Nonoperative improvements in range of motion vary widely but have been reported anywhere from 10 to 50 degrees or more. O’Driscoll described four stages of elbow stiffness:

- **Bleeding**: minutes to hours
- **Edema**: hours to days. Both bleeding and edema cause swelling within the joint and surrounding tissues, and the tissues become biomechanically less compliant. Early elbow range of motion through an entire range during stages 1 and 2 can prevent stiffness.
- **Granulation tissue**: days to weeks. Splints can be used to regain range of motion.
- **Fibrosis**: Maturation of the granulation tissue further decreases compliance. More aggressive splinting is necessary, along with possible surgical management.

**SURGICAL MANAGEMENT**

- The key is to identify the functional disability of the patient—pain, loss of motion, or both—and what would be most beneficial.
- The indications include a loss of function to preclude the patient from performing ADLs and occupational or vocational activities.
- Arthroscopic treatment of elbow stiffness should be undertaken only if the offending structures can be treated from an arthroscopic approach. Heterotopic ossification is not amenable to arthroscopic treatment.
- Appropriate counseling with the patient should cover realistic expectations of range of motion and functional recovery. Will patients be able to get their hand to their mouth, comb their hair, or reach behind their back, or are more extensive demands required?

**Preoperative Planning**

- The surgeon should assess for heterotopic ossification on plain radiographs. Arthroscopic treatment is not indicated if this is causing the contracture.
- An examination under anesthesia helps to confirm nonmuscle-related pathology and to assess the static component of contraction, which should mirror the in-office examination.
- If the examination documents irritation or neuropathy, the ulnar nerve should be exposed and released.
- We recommend that the ulnar nerve be released before the arthroscopic portion for ease of dissection before fluid distention.
- In patients with elbow flexion of less than 100 degrees and in those with ulnar nerve tension signs or sensitivity to percussion, the nerve should be prophylactically released to prevent compression once flexion is restored postsurgically.
- The surgeon must ensure that the ulnar nerve cannot be subluxated or transposed.
- Contraindications to arthroscopic release are prior surgery that has altered the neurovascular anatomy, joint deformity that would compromise arthroscopic view, prior ulnar nerve transposition, and malunited elbow fractures.

**Positioning**

- Either the lateral decubitus or prone position can be used.
- Lateral decubitus: well-padded pillow at edge of beanbag underneath elbow antecubital fossa
- Prone: adequate chest and arm support, shoulder abducted to 90 degrees
- Well-padded sterile tourniquet for either position
The remainder of the arthroscopic setup has been described elsewhere.

The surgeon should clearly mark the course of the ulnar nerve, portal sites, and bony landmarks with surgical marker (FIG 4C).

**Approach**

- As with any arthroscopy, the surgeon must be able to visualize the joint.
- O’Driscoll states that the single most important factor to improve visualization is the use of arthroscopic retractors.  
- Loss of volume makes this difficult, but it can be facilitated with the use of elbow arthroscopic retractors.
- The key is to avoid nerve injury during the approach and during capsular treatment.
- The surgeon should plan for intraoperative ulnar nerve release if indicated. Nerve decompression is performed before arthroscopy because fluid extravasation distorts the surgical tissue planes (FIG 5).

**PORTAL ESTABLISHMENT IN CONTRACTED ELBOW**

- The joint is distended with saline through the “soft spot” portal (up to 20 mL, less depending on contracture).
- Portals are established.
  - The 4.5-mm, 30-degree arthroscope is used through a proximomedial portal (about 2 cm proximal to the medial epicondyle and just anterior to the medial intermuscular septum) (TECH FIG 1A,B).  
  - The proximolateral portal (1.5 to 2 cm proximal to lateral epicondyle) is identified with either a blunt-tipped Wissinger rod or a spinal needle using an outside-in technique. Retractors are used to improve distention and visualization (TECH FIG 1C).
- Blunt dissection techniques with the Wissinger rod are used to obtain a working space.
- A 4.5-mm shaver (oscillate function) removes more material from the working space, but not yet the capsule.
- A small radiofrequency device can be used to débride the scar tissue within the joint. Inflow should be increased during the use of thermal energy.
- The capsule is not removed until the tissue planes are better defined to minimize nerve injury risk. The capsule is débrided superficially to define it as a structure.
TECH FIG 1 • A. Arthroscopic view of a right elbow joint after first obtaining scope entry into the proximomedial portal, looking laterally. There is synovitis in the joint. B. After the synovitis is gently débrided with an arthroscopic shaver, the bony overgrowth of the coronoid and radial fossa is revealed. There is a lack of concavity in the trochlea and capitellum area. C. Arthroscopic view of elbow joint viewed from the medial portal, showing the increased visualization of the elbow joint that is obtained with the use of intra-articular retractors. C, capitellum; RH, radial head; T, trochlea.

TECH FIG 2 • A. Arthroscopic view of the elbow joint after capsulectomy and deepening of the coronoid and radial fossa. The dissection is carried down to the fibers of the brachialis muscle but does not violate the brachialis (retracted structure). B. View from the lateral portal shows the partially completed release. Bony work and resection are completed before capsulectomy. The concavity in the coronoid and trochlear fossa areas is formed, but anterior capsulectomy is not yet completed. AC, anterior capsule; C, capitellum; RH, radial head; T, trochlea.

ANTERIOR CAPSULAR RELEASE

- Capsulotomy of the anterior capsule is performed with an arthroscopic basket cutter.
- The brachialis muscle can be visualized and the plane between the capsule and brachialis developed from the lateral working portal (TECH FIG 2A).
  - The brachialis protects the median nerve, so the surgeon should avoid penetrating this muscle.
  - The surgeon continues incising the capsule from lateral to medial.
  - The capsulotomy should be continued to the level of the collateral ligaments on each side, but the ligaments are not incised.
- The lateral side is at risk of injuring the radial nerve behind the capsule (just anterior to the radial head).
- Capsulectomy in this area, although it may improve the results, carries a higher risk for radial nerve injury. It may be safest to remove the capsule well proximal to the joint line on the lateral side to avoid this risk.
- The posterior interosseous nerve is the most significant nerve at risk during elbow arthroscopy.16 It is adjacent to the anterolateral capsule (distally).
- The surgeon should view from the lateral portal to ensure adequate medial release (TECH FIG 2B).

POSTERIOR CAPSULAR RELEASE

- The surgeon establishes a posterocentral portal for the arthroscope (4 cm proximal to the olecranon tip through the triceps) and a posterolateral working portal (2 cm proximal to the olecranon tip and lateral to the triceps).
- A shaver is used to débride and open the space and remove loose bodies and osteophytes. Suction is avoided in and along the medial gutter.
- The capsule is elevated from the distal humerus (using a shaver or elevator).
The posterior capsule is released with a basket cutter or arthroscopic elevator on the medial and lateral sides; the surgeon stops before the medial aspect of the olecranon fossa (to avoid injury to the ulnar nerve).

The posteromedial capsule should be resected in the setting of significant flexion loss (posterior band of the medial collateral lateral) and is the floor of the cubital tunnel.

Final inspection from both portals is done to ensure adequate release (TECH FIG 3).

Loose bodies are removed via a 5-mm-smooth cannula.

Subcutaneous transposition or in situ decompression of the ulnar nerve can be performed.

As advocated by O’Driscoll, the ulnar nerve is exposed before performing the arthroscopic release to allow gentle fluid extravasation from the soft tissue posteromedially.

Gentle retraction on the nerve can help protect it while performing arthroscopic releases in this area.

At the end of the case the ulnar nerve can be released using a variety of described techniques.

A drain is placed through the proximal anterolateral portal because accumulation of fluid will compromise range of motion.

Our postoperative dressing is a bulky dressing with Webril, Kerlex, and Ace bandage from wrist to shoulder with material cut out in the antecubital fossa to facilitate immediate continuous passive motion (CPM).

Alternatively, an anterior plaster slab over the elbow is used with the forearm in full extension (TECH FIG 4).

Indwelling catheters or a long-acting regional block may be used to facilitate CPM (from full flexion to extension), which should start in the hospital.

Before starting CPM, the dressing is changed to a soft, noncompressive gauze to prevent skin complications.

Postoperative dressing is applied to the patient after capsular release in the operating room with a drain. Flexion obtained after removing splint material from the antecubital fossa. Immediate continuous passive motion is instituted.
In the medial aspect of elbow joint, the surgeon should retract medially and resect along the radiocapitellar articulation. The surgeon should use care with the capsule just anterior to the midline of the brachialis muscle. Generous retraction and retractors are used inside the joint. Iatrogenic injury is avoided by not penetrating the brachialis muscle.

Prophylactic release if contracture is significant. The surgeon should err on the aggressive side when in doubt.

The surgeon should avoid motorized burrs. No suction should be used on the shaver in risk areas. Generous retraction and retractors are used inside the joint.

The surgeon should use care with the capsule just anterior to the midline of the radiocapitellar articulation. The surgeon should not penetrate the brachialis muscle.

The surgeon should consider prophylaxis of heterotopic ossification with indomethacin.

It is difficult to compare arthroscopic versus open capsular releases.

Compared to open series, Savoie and Field \(^1\) reported on 200 patients with capsular release: there was a mean improvement in extension of −46 degrees to −3 degrees and flexion of 96 degrees to 138 degrees, with a decrease in pain scale score from 6.5 to 1.5.

Radial or posterior interosseous nerve palsy
- Iatrogenic injury can be avoided by avoiding suction in high-risk areas.
- Retractors of soft tissue are used to improve visualization and distention.
- The surgeon should use care when anterior to midline of radiocapitellar articulation in the capsule.

Median nerve
- Iatrogenic injury is avoided by not penetrating the brachialis muscle.
- The surgeon should place portals carefully, avoiding anterior.

Ulnar nerve
- In the medial aspect of joint, the surgeon should use retractors to move the capsule medially.
- Transposition before the case may aid in ulnar nerve protection and also allow fluid extravasation.

Postoperatively it may be transient; there is a much lower incidence if it is transposed during initial surgery.

Excessive bone resection, especially of radial head
- The surgeon should avoid excessive resection.

Ulnar neuritis
- If present preoperatively, ulnar nerve release should be ensured.

References
DEFINITION
- Primary degenerative arthritis of the elbow joint is a relatively rare condition.9,18
- Patients with primary osteoarthritis of the elbow are frequently manual laborers, athletes, and those who rely on wheelchairs or crutches for ambulation.4,15,18,21
- Although total elbow arthroplasty provides pain relief and improved range of motion in patients with inflammatory arthritis and or low demands, use in young active patients has been associated with early loosening and is undesirable in this group. Likewise, elbow arthrodesis is undesirable to many patients who do not wish to sacrifice motion in favor of pain relief.8
- Open débridement procedures have been described and used with good success.3,4,6,9,14,16,22,23
- Arthroscopic procedures have gained acceptance with patients and surgeons for perceived benefits of a minimally invasive nature and better visualization of the joint.
  - More series are confirming results at least equivalent to open procedures, with similar complication rates.
  - Arthroscopic débridement and osteocapsular resection is a procedure that adequately addresses the underlying pathologic processes and is associated with early return to activities, a durable result that does not preclude future reconstructive procedures, and minimal perioperative morbidity.2,10,11,12,17,20

ANATOMY
- At the elbow, the coronoid fossa anteriorly, the trochlea, and the olecranon fossa posteriorly articulate with the coronoid and olecranon. Bony osteophytes may develop, leading to impingement in flexion and extension in degenerative conditions.

PATHOGENESIS
- Three main pathologic processes are involved in primary elbow arthritis. Loss and fragmentation of cartilage lead to loose body formation. Osteophytes arise from reactive bone formation.
  - These two processes cause impingement and contribute to the third process, progressive joint contractures.21,22 The capsule becomes abnormally thickened and contracted.
  - Symptoms include loss of extension, pain at the end points of motion, and mechanical symptoms such as catching or locking.4,9
  - Other commonly associated conditions include cubital tunnel syndrome with paresthesias and weakness in the ulnar distribution and decreased grip strength.4,13

NATURAL HISTORY
- The natural history is one of slowly progressive joint contracture and discomfort. Ulnar neuritis may develop.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The typical patient is a middle-aged male laborer with a painful dominant elbow, worse with use.
  - Less frequently, patients who depend on wheelchairs or crutches for mobility, and who thus put increased forces across their elbow joints, may be afflicted.
  - Progressive loss of motion and pain at the extremes of motion due to impingement of osteophytes are noted.
  - Painful crepitus and catching or locking sensations may be noted with range of motion. Usually pain in the mid-arc of motion is absent.
  - Patients with contracture of the posterior capsule will lack flexion, whereas those with anterior contractures will lack extension.
  - Not infrequently, ulnar nerve irritation is noted. This should be documented and will contribute to decision making regarding the need for decompression or transposition.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Usually plain film radiographs, clinical examination, and history are sufficient to make the diagnosis (FIG 1).
- Radiographs may show joint space narrowing, hypertrophic bony osteophytes, loose bodies, and subchondral sclerosis typical of osteoarthritis.

DIFFERENTIAL DIAGNOSIS
- Usually it is easy to exclude inflammatory arthropathies and posttraumatic arthritis, which may also be treated with this technique.

FIG 1 • AP and lateral radiographs of the typical patient with degenerative arthritis of the elbow. Bony osteophytes are noted with loose body formation.
Physical examination will also exclude other painful elbow conditions, such as tendinitis, instability, or cubital tunnel syndrome.

NONOPERATIVE MANAGEMENT
- Operative treatment should be considered only after exhausting conservative measures, which include activity modification and nonsteroidal anti-inflammatory medications.17

SURGICAL MANAGEMENT
- Patients who have failed to respond to nonoperative management and desire improved range of motion and pain relief may be surgical candidates.

Preoperative Planning
- Careful physical examination with attention to neurovascular status should be documented.
- Routine radiographs are usually all that are necessary.

Positioning
- General endotracheal anesthesia is induced and the patient is placed in the lateral decubitus position.
- The arm is secured in a dedicated arm holder, ensuring free access to the elbow with instruments (FIG 2A).
  - Positioning the elbow just higher than the shoulder allows free access to the elbow.
- A nonsterile tourniquet is applied and the arm is prepared and draped in the usual fashion (FIG 2B).

Approach
- Patients with lack of flexion will need to have the posterior aspect of the joint addressed; patients with lack of extension will require release and débridement anteriorly. Either compartment may be addressed first, depending on the pathology present.
- The standard arthroscopic setup and equipment includes the 4-mm 30-degree arthroscope.
  - A 2.7-mm arthroscope can be used, but in most cases the joint can accommodate a 4-mm arthroscope.
- A 70-degree arthroscope may likewise be used but is usually not necessary and may be awkward unless the surgeon has experience using this arthroscope.
- Only blunt, not sharp, trocars should be used.
- Retractors such as a Howarth elevator or a large blunt Steinmann pin make the procedure easier and enhance visualization. Commercially available retractors are now available.
  - The standard arthroscopic shaver and burr are used.
  - Suction should be placed to gravity only to prevent accidentally shaving objects that may be sucked into the shaver (FIG 3).
- The portal sites and landmarks, including the radial head, medial and lateral epicondyles, capitellum, and olecranon, should be marked before insufflation of the joint, which may obscure landmarks.
- The ulnar nerve should be examined and its location marked; the surgeon should watch for a subluxating ulnar nerve.
  - If prior surgery has been performed or there is any question of the nerve’s location, a small incision may be made to identify and retract the nerve to protect it against inadvertent injury.
ANTERIOR PORTAL PLACEMENT

- The surgical technique for arthroscopic elbow débridement and capsular release involves the standard arthroscopic technique and setup as previously described.  
- The joint is distended with 20 to 30 mL of saline introduced via an 18-gauge needle through the “soft spot” (the center of a triangle formed by the olecranon process, the lateral epicondyle, and the radial head). This makes entry into the joint easier to achieve.
- Portal sites are established according to the order preferred by the surgeon; the procedure described below is our preference.
- Portal sites are made by incising the skin only with a no. 11 blade, and then blunt dissection with a hemostat proceeds to the joint.
  - Capsular entry and joint location is confirmed by sudden egress of fluid.
  - The blunt trocar and sleeve are then placed into the joint and exchanged for the arthroscope.
- The anterolateral portal (TECH FIG 1A) is established first, with care taken to avoid and protect the radial nerve.
  - This portal is established just anterior to the sulcus between the capitellum and the radial head.
  - The anteromedial portal is established using an inside-out technique with direct visualization.
  - The arthroscope is removed and replaced with the blunt trocar, which is pushed directly across the joint until it tents the skin overlying the medial side of the elbow.
  - The skin is incised over this region and the trocar pushed through the remaining soft tissue.
  - A cannula may be placed over the trocar on the medial side, and the trocar is pulled back into the joint and out the lateral side (TECH FIG 1B).
  - A proximal anterolateral retraction portal may be established about 2 cm proximal to the lateral epicondyle.

ANTERIOR PORTAL PLACEMENT

- The anterolateral portal (TECH FIG 1A) is established first, with care taken to avoid and protect the radial nerve.
- This portal is established just anterior to the sulcus between the capitellum and the radial head.
- The anteromedial portal is established using an inside-out technique with direct visualization.
- The arthroscope is removed and replaced with the blunt trocar, which is pushed directly across the joint until it tents the skin overlying the medial side of the elbow.
- The skin is incised over this region and the trocar pushed through the remaining soft tissue.
- A cannula may be placed over the trocar on the medial side, and the trocar is pulled back into the joint and out the lateral side (TECH FIG 1B).
- A proximal anterolateral retraction portal may be established about 2 cm proximal to the lateral epicondyle.

ANTERIOR CAPSULECTOMY AND ARTHROSCOPIC DÉBRIDEMENT

- A 4.8-mm arthroscopic shaver is introduced through the anteromedial portal with retraction via a proximal anterolateral portal.
- Shaving proceeds to gain visualization.
- The anteromedial capsule is then stripped off the humerus to expand space in the contracted joint.
- Loose bodies are removed as they are identified. Osteophytes are removed with the shaver and burr from the coronoid and radial head fossae.
- After completion of the bony débridement, the anterior capsule is completely resected under direct visualization with the arthroscope in the lateral portal site.
- The biter is used to gain a free edge of the anterior capsule, proceeding from medial to laterally and halting when the fat pad anterior to the radial head is encountered.
- The shaver is used to completely resect the anterior capsule.
- The arthroscope is placed in the medial portal and bony débridement and capsulectomy is completed.

POSTERIOR PORTAL PLACEMENT

- After completing the anterior joint débridement and capsulectomy, attention is turned to the posterior aspect of the joint.
- Again, the location of the ulnar nerve is established and marked (see Tech Fig 1B).
- The posterolateral portal is used for visualization.
  - It is made with the elbow in a 90-degree flexed position and is placed at the lateral joint line at a level with the tip of the olecranon.
- The direct posterior portal is the working portal. It is made 2 to 3 cm proximal to the tip of the olecranon. It penetrates the thick triceps, and a knife should be used to establish this portal.
- Optional posterior retractor portals include one placed 2 cm proximal to the direct posterior portal, situated either slightly medially or laterally.
POSTOPERATIVE CARE

- After the procedure, motion is assessed (FIG 4), the portals are closed in the standard fashion with 3-0 nylon or Prolene sutures, and a sterile compressive dressing applied.
- A posterior slab of plaster is used to splint the operative extremity in full extension, and the arm is elevated in the “Statue of Liberty” position overnight.
- On postoperative day 1, the splint is removed and the neurovascular status is evaluated, with particular attention to the radial, median, and ulnar nerves.
- Full active range of motion is initiated. No limitations are placed on use of the arm.
- Continuous passive motion may be initiated using a continuous passive motion device with or without a nerve block; however, in our experience it is not usually necessary.
- In patients who cannot practice motion on their own or in those with severe contractures, it may be of benefit, although a consensus regarding the indications and need for continuous passive motion is lacking.

OUTCOMES

- In our series, outcomes after the described procedure in 41 patients and 42 elbows were reviewed after an average follow-up of 176.3 weeks (minimum 2 years of follow-up).
- Significant improvements in mean flexion (from 117.3 degrees preoperatively to 131.6 degrees, \( P < 0.0001 \)), extension (from 21.4 degrees to 8.4 degrees, \( P < 0.0001 \)), supination (from 70.7 degrees to 78.6 degrees, \( P = 0.0056 \)), and Mayo Elbow Performance Index scores (\( P < 0.0001 \)) were noted, with 81% good to excellent results.
Pain decreased significantly ($P < 0.0001$).
Complications were rare (n = 2; heterotopic ossification and transient ulnar dysthesias).
Cohen et al$^5$ compared outcomes after arthroscopic débridement versus open débridement of the elbow for osteoarthritis, using the Outerbridge-Kashiwagi procedure and an arthroscopic modification.
Both groups showed improved range of elbow flexion, decrease in pain, and a high level of patient satisfaction.
Increases in elbow extension, although improved in both groups, were more modest.
Neither procedure included capsular release.
Comparison between the open and arthroscopic procedures showed that the open procedure might be more effective in improving flexion, whereas the arthroscopic procedure seemed to provide more pain relief.
No differences between overall effectiveness of the two procedures were noted.
From these series and others in the literature, it appears that arthroscopic débridement and capsular release have similar outcomes with respect to pain relief, improved range of motion, and complications. Although the use of arthroscopic procedures is attractive to decrease morbidity, benefits over open procedures have not been proved.

COMPLICATIONS
With any arthroscopic or open procedure about the elbow, the risk of neurovascular injury is a real concern.
In a series from the Mayo Clinic,$^7$ 50 complications were observed after 473 elbow arthroscopies for a variety of interventions.
Most frequently, this included prolonged wound drainage; other complications included infection, nerve injury, and contractures.
No permanent nerve injuries were observed.
Nevertheless, injuries of each of the susceptible nerves about the elbow joint have been observed.
Careful attention intraoperatively, appropriate portal placement, and knowledge of anatomy will help prevent injury.

Arthroscopic Treatment of Epicondylitis

Kevin P. Murphy, Jeffrey R. Giuliani, and Brett A. Freedman

DEFINITION

- Epicondylitis is overuse tendinosis at the elbow, with pain localized to the origin of the lateral common extensor mass or, much less commonly, the origin of the medial common flexor mass.
- Lateral epicondylitis (LE), also known as tennis elbow, is the most common overuse injury of the elbow, resulting from repetitive microtrauma at the origin of the extensor carpi radialis brevis (ECRB).
- The hallmark clinical finding is pain localized to the lateral aspect of the elbow reproducible with resisted wrist extension and forearm supination.
- Medial epicondylitis results from repetitive valgus forces at the elbow, with tendinosis commonly localized to the origins of the flexor carpi radialis and pronator teres, with tenderness slightly anterior and distal to the medial epicondyle.
- Nonoperative management is the initial treatment of choice for epicondylitis. It is successful in 90% to 95% of patients.3,10 Nonetheless, for the 5% to 10% of LE patients who fail to respond to nonoperative management and develop chronic refractory symptoms, the senior author’s (KPM) treatment of choice since 1995 has been arthroscopic release.
- Cadaveric and anatomic studies have shown that elbow arthroscopy and ECRB release is safe, reliable, and reproducible.7,11
- The treatment of choice for refractory medial epicondylitis is open débridement of pathologic tissue of the flexor pronator origin. This will not be discussed in this chapter.

ANATOMY

- The common extensor tendon origin represents the confluence of four tendons: ECRB, extensor digitorum communis, extensor digiti minimi, and extensor carpi ulnaris.
- The ECRB origin is on the distal anterolateral aspect of the lateral epicondyte. It covers an area of about 1.5 cm and lies deep to the other three muscles of the extensor mass.
- Arthroscopically, the ECRB is the muscle belly and tendon that can be seen lying just superficial to a thinned-out portion of the lateral joint capsule.
- The extensor carpi radialis longus actually originates from the lateral humeral supracondylar ridge, 2 to 3 cm superior to the common extensor tendon, and then passes distally, anterior, and superficial to the ECRB.
- The lateral ulnar collateral ligament is deep to the extensor tendons and originates from the lateral epicondyle, reinforcing the lateral joint capsule as well as inserting onto the annular ligament and supinator ridge of the ulna.

PATHOGENESIS

- The actual pathophysiology of LE is still not completely understood, and minimal advances in our knowledge of the disease process have occurred in the past 2 years.
- Proposed causes include bursitis, synovitis, ligament inflammation, periostitis, tendinitis, tendinosis, and extensor tendon tears.
- It is widely accepted that LE is not an “itis” or inflammatory condition but rather a tendinosis.
- The most commonly accepted cause today is tendinosis as a result of microscopic tearing of the ECRB muscle with repetitive trauma that causes ingrowth of weakened reparative tissue known as angiofibroblastic hyperplasia or angiofibroblastic tendinosis.
- The process of repetitive micro- and macrotearing can ultimately lead to a spectrum of ECRB tendinosis ranging from fraying to complete tendon failure if the condition is not addressed early.6

NATURAL HISTORY

- Epicondylitis responds to conservative management in 90% to 95% of cases.
- If treated in the acute setting with activity modification, in conjunction with other conservative modalities, nonsteroidal anti-inflammatory medication may contribute to the alleviation of symptoms experienced with acute LE.
- With progressive repetitive trauma, fraying of the tendon and microtears can progress to macroscopic tears and fibrillations of the ECRB, which ultimately could lead to complete tendon rupture or avulsion.
- If the lateral joint capsule is involved in chronic LE, it can avulse along with the ECRB tendon and create a lateral synovial cyst or a sense of lateral joint instability.
- Chronic refractory LE originates in the ECRB tendon, but it could extend to involve the anterior portion of the extensor digitorum communis, which may ultimately lead to weakness with wrist extension and supination.
- Baker et al2 have published an arthroscopic classification system for LE that we have found to be reliable (Table 1).
- Rarely, in the chronic setting, treatment may require tendon transfer surgery to restore long extensor function.

ECRB, extensor carpi radialis brevis.
PATIENT HISTORY AND PHYSICAL FINDINGS
- The pain associated with LE can be secondary to an acute event, but most commonly it is insidious in onset—the result of repetitive microtrauma.
- Patients typically report pain with resisted wrist extension and supination with the elbow extended.
- It is important to ask the patient about length and type of conservative treatment, history of corticosteroid injections, and response to prior therapy.
- Patients who have had a good or excellent initial response to steroids, followed by reaggravation of symptoms, may have resumed strenuous activities too soon or too abruptly and may respond to an additional trial of nonoperative management.
- A prior surgical history of the involved elbow is extremely important for operative planning and can contribute to the diagnosis. Furthermore, a history of a prior ulnar nerve transposition could place the ulnar nerve at risk when establishing arthroscopic portals and may require an open approach.
- The physical examination should include:
  - Palpation of the lateral epicondyle—common extensor mass; the surgeon should document the exact location of tenderness to palpation, which is critical for differential diagnosis. This is the most predictive examination for LE.
  - Resisted wrist extension: Pain with resisted middle finger extension is commonly present in patients with LE but can also be diagnostic for posterior interosseous nerve (PIN) syndrome.
  - Resisted supination and grip strength: Grip strength is diminished in 78% of patients with LE. Resisted supination elicits pain in 51% of patients. The differential includes bicep tendinitis. Pain with turning a doorknob can also indicate LE.
  - Chair test: The test is positive when a patient refuses or is unable to lift a chair with the arms forward flexed, elbows and wrists in extension, and forearms in pronation.
  - The differential diagnosis for lateral elbow pain is long, so it is pertinent to perform a thorough physical examination of both the ipsilateral and contralateral upper extremity, as well as the cervical spine.
  - The differential diagnosis of lateral elbow pain includes (but is not limited to) the following:
    - Compressive neuropathy of the radial nerve—radial tunnel syndrome or PIN. The point of maximal tenderness in both radial tunnel syndrome and PIN syndrome is more distal than in LE. PIN syndrome presents with a motor palsy, whereas LE is a diagnosis of pain. Radial tunnel syndrome can be tested for specifically with the resisted middle finger extension test. Selective injections and electrodiagnostics can confirm the diagnosis.
    - Posterolateral rotatory instability is caused by an injury to the lateral ulnar collateral ligament. Although posterolateral rotatory instability can be associated with mechanical symptoms, the lateral pivot shift test can clinically differentiate instability from epicondylitis.\(^8,10\)
    - Osteoarthritis, particularly in the radiocapitellar joint
      - The physical examination usually causes mechanical symptoms and decreased range of motion.
      - Radiographs confirm sclerosis, osteophyte formation, loose bodies, and joint space narrowing of the radiocapitellar joint.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs have been of limited benefit in the diagnosis of LE but should be obtained to rule out other causes of pain or coexisting pathology, especially in recalcitrant cases.
- Radiographic evaluation of the elbow in a patient with lateral elbow pain should be limited to an anteroposterior view in full extension and a lateral view with the elbow flexed at 90 degrees.
- One study reports an incidence of calcification about the ECRB origin from chronic tendinosis in up to 25% of patients (FIG 1A).\(^9\)
- Historically, magnetic resonance imaging (MRI) has had limited utility in the diagnosis of LE.
- MRI can demonstrate ECRB tendon thickening, increased signal on T1 and T2 images, and in advanced disease high T2-signal cystic areas that correspond to partial or complete ECRB avulsions or large areas of mucoid degeneration, which are nonspecific findings for LE (FIG 1B).
- Despite its limited specificity for LE, MRI can be a useful, noninvasive technique to visualize concomitant intra-articular elbow pathology and soft tissue pathology.

DIFFERENTIAL DIAGNOSIS
- Lateral
  - Radiocapitellar chondromalacia
  - Osteochondral loose bodies
  - Radial head fracture
  - Osteochondritis dissecans lesion
  - PIN entrapment
- Medial
  - Inferior cruciate ligament strains or tears
  - Medial epicondyle avulsion fracture
  - Ulnar neuritis
  - Ulnar subluxation
  - Medial epicondylitis
  - Osteochondral loose bodies
  - Olecranon stress fracture
  - Valgus extension overload syndrome
  - Pronator teres syndrome

FIG 1 • A. Standard AP radiograph of the elbow showing calcification of the extensor carpi radialis brevis (ECRB) tendon. B. T1-weighted MRI of the elbow. Arrows show intermediate or high signal intensity of the ECRB tendon at its insertion site on the lateral epicondylitis.
Anterior
- Anterior capsular strain
- Distal biceps tendon strain
- Brachialis strain
- Distal biceps tendon rupture
- Coronoid osteophyte
Posterior
- Valgus extension overload syndrome
- Triceps tendinitis
- Triceps tendon avulsion
- Pronator teres syndrome
- Olecranon stress fracture
- Osteochondral loose bodies
- Olecranon bursitis

NONOPERATIVE MANAGEMENT
- LE responds to conservative management in 90% to 95% of cases.
- Treatment algorithms and modalities are extensive and include rest, activity modification, anti-inflammatory medication, phonophoresis, iontophoresis, massage, stretching, strengthening, counterforce bracing (tennis elbow wraps), sporting equipment modification, acupuncture, extracorporeal shock wave therapy, and corticosteroid injections.
- No single nonoperative protocol has proved to be the best, and there is a severe paucity in empiric support for any modality.
- Realizing that the natural history of LE appears to be one of spontaneous resolution for most patients within 6 to 12 months, rest and removal of the offending overuse activity is probably the most important component in the initial treatment of LE.
- While steroid injections and nonsteroidal anti-inflammatory medications have been recommended in the treatment of LE, there is little to no empiric evidence to support their use.
- A three-stage rehabilitation program with the most widespread acceptance entails rest to reduce pain, counterforce bracing followed by progressive wrist extensor strengthening, and a delayed resumption of inciting activities.
- Extracorporeal shock wave therapy has been the most clinically studied nonoperative modality in the past 2 years.
  - It is difficult to clearly define its role in the treatment of LE given the conflicting results in several studies, along with the relatively short-term follow-up data currently available.
  - We believe extracorporeal shock wave therapy should be considered a possible alternative to surgery for refractory cases only. It is not a first-line therapy at this point.

SURGICAL MANAGEMENT
- Despite 3 to 6 months of nonoperative management, approximately 5% to 10% of patients develop recalcitrant symptoms that may require surgical intervention.
- The surgical options include open, percutaneous, and arthroscopic surgical techniques, with success rates that vary from less to 65% to 95% good or excellent outcomes.
- The pervasive move toward minimally invasive surgical techniques and the desire for a quick return to full activity have resulted in research and development of safe and effective means for performing arthroscopic releases for LE.
- In comparison with open procedures, arthroscopy has several distinct advantages, including the ability to address intra-articular pathology, preservation of the superficial common extensor origin and therefore grip strength, faster return to work and sports-related activities, and lower morbidity.
- Arthroscopy appears to combine the best attributes of the earlier return to activity seen with percutaneous procedures and the decreased recurrence rates commonly reported with open procedures.

Preoperative Planning
- The surgeon must review radiographs and imaging studies for concomitant pathology such as osteochondral loose bodies, radiocapitellar arthritis, fracture, and injury to surrounding soft tissue structures like the lateral collateral ligament complex.
- Under general anesthesia
  - The lateral pivot shift test, described by O’Driscoll, tests the elbow for a lateral ulnar collateral ligament injury by stressing the elbow in supination, and valgus and axial compression as the elbow is moved from full extension over the patient’s head to 20 to 40 degrees of flexion.
  - Posterolateral rotatory instability is diagnosed when the radiocapitellar joint subluxes, creating a sulcus proximal to the radial head.
  - In addition, the surgeon must examine the range of motion of the elbow under anesthesia in full flexion and extension, pronation and supination.
  - Examination findings under anesthesia should always be compared with the contralateral extremity.

Positioning
- The patient is placed in the prone position on the operating table in the standard fashion.
- The operative elbow is flexed at 90 degrees and hangs over the bed to gravity. A sandbag may be placed under the operative extremity to maintain elbow flexion.
- The surgeon is seated for the procedure.

Approach
- As stated previously, LE can be treated with a multitude of well-described open or percutaneous procedures with the goal of débride diseased tissue.
- Techniques include partial epicondylectomies, partial resection of the annular ligament, and lengthening (slides) of the extensor tendons.
- Our bias is toward arthroscopic treatment.
- Numerous arthroscopic portals have been described for elbow arthroscopy, but nine are most commonly used: two medial, four lateral, and three posterior.
- When addressing LE, the surgeon must be able to perform a diagnostic arthroscopy of the anterior compartment of the elbow and be able to visualize, evaluate, and address pathology of the lateral capsule and the undersurface of the ECRB tendon.
- Absolute contraindications to elbow arthroscopy are distortion of normal bony or soft tissue anatomy that precludes safe portal placement, previous ulnar nerve transposition or hardware that interferes with medial portal placement, or local cellulitis.
- Although LE could be addressed through a combination of the different medial and lateral portals, we have had the most success avoiding injury to neurovascular structures and improving visualization with the proximal anteromedial portal as...
Once the patient is positioned, prepared, and draped and the surgical landmarks are drawn, the joint is distended using an 18-gauge needle to inject 20 mL of saline via the direct lateral approach into the joint (TECH FIG 1).

The proximal medial portal is established first. This is the viewing portal and allows for the proximal lateral portal to be created under direct arthroscopic visualization.

The surgeon makes a 2-mm longitudinal skin incision using a no. 11 scalpel blade, 2 cm proximal and 2 cm anterior to the medial epicondyle.

This incision should go no deeper than the skin to protect the cutaneous nerves and veins.

Alternatively, the arthroscope light can be used to transluminate the skin and identify these structures so that they can be avoided before making the skin incision.

A hemostat is inserted through the subcutaneous tissue, onto the medial humeral condylar ridge, and down to the medial capsule, using blunt dissection.

The capsule is robust and a pop should be felt as it is entered.

Some of the normal saline that was previously injected to inflate the joint will now be released through the portal site, further confirming entry into the joint.

Staying anterior to the medial intermuscular septum protects the ulnar nerve from danger.

Next, a blunt trocar is introduced into the joint, followed by the 4-mm, 30-degree arthroscope.

The anterior compartment of the elbow should be diagnosed for pathology (osteoarthritis, loose bodies, capsuloligamentous flaps or redundancies); these will be addressed once the proximal lateral portal is established.

After the anterior compartment has been inspected, attention is directed toward the lateral capsule and ECRB tendon.

An 18-gauge spinal needle is inserted 2 cm proximal and 2 cm anterior to the lateral epicondyle.

Using techniques for skin and soft tissue management similar to those described for the proximal medial portal placement, the proximal lateral portal is made under direct arthroscopic visualization.

The radial nerve is the structure most at risk with this portal.

With the proximal medial portal as the standard viewing portal, the 30-degree scope is advanced just past the radial head to visualize the lateral joint capsule and undersurface of the ECRB origin (TECH FIG 2A).

The capsule often adheres to the undersurface of the ECRB and can have varying degrees of degeneration, presenting as linear tears (type II lesion), fraying, or yellowish fatty infiltration, or it can have a thin, translucent appearance (TECH FIG 2B).

If the capsule is intact, it is débrided using a 4.5-mm synovial shaver inserted in the working portal—the proximal lateral portal.

The capsule and tendon may be completely avulsed and retracted; this is classified as a type III lesion (TECH FIG 2C).

The undersurface of the ECRB is in plain view once the capsule is débrided.

The release of the muscle should begin at the site of degeneration or tear using a 4.5-mm incisor (TECH FIG 2D).
Next, the surgeon progresses proximally to the ECRB origin on the lateral epicondyle.
- Care must be taken to avoid injury to the articular surface of the capitellum or radial head during this process (TECH FIG 2E).
- Just superficial to the ECRB the extensor carpi radialis longus will come into view (TECH FIG 2F).
- A 4.0-mm abrader is placed in the proximal lateral portal to débride the remaining origin of the ECRB and to decorticate the lateral epicondyle and distal lateral condylar ridge to promote healing (TECH FIG 2G).
- The cadaveric model by Kuklo et al? showed that using this technique, an average of 23 mm of ECRB tendon and 22 mm of lateral epicondyle can be safely resected.
- In addition, the 30-degree scope field of visualization avoids injury to the lateral ulnar collateral ligament, which is posterior to an intra-articular line bisecting the head of the radius.¹¹

If needed, a direct lateral portal can be made when the elbow is flexed 90 degrees for access to the posterior compartment.
- This portal enters the soft tissue triangle created by the radial head, the lateral humeral epicondyle, and the olecranon.
- The medial antebrachial cutaneous nerve is the structure at risk with this portal.
- Once the arthroscope is introduced into the joint, the elbow is extended and the scope is advanced into the posterior compartment.
- If a working portal is needed, a direct posterior portal can be placed midline between the medial and lateral epicondyles about 3 cm proximal to the olecranon tip.
- The joint is expressed free of all arthroscopic fluid, portals are closed with figure 8 3-0 nylon sutures, and a soft tissue dressing is applied.
PEARLS AND PITFALLS

| Indications | ■ Indication for arthroscopic release is pain that lasts longer than 3 to 6 months despite a trial of nonoperative methods (rest, counterforce bracing, stretching, and strengthening). |
| Absolute contraindications | ■ Distortion of normal bony or soft tissue anatomy that precludes safe portal placement  
■ Previous ulnar nerve transposition or hardware that interferes with medial portal placement  
■ Osteomyelitis or local cellulitis |
| Neurovascular injury | ■ Neurovascular injury is avoided by using the “nick and spread” technique:  
■ An 11-mm arthroscopic blade placed through the skin is used to pull skin distally for small incision.  
■ A hemostat is used to bluntly dissect to the capsule.  
■ A 2.7-mm arthroscopic blade is used rather than a 4.0-mm arthroscope.  
■ If a 4.0-mm scope is desired, the joint is entered over a switching stick.  
■ A postoperative intra-articular injection is not recommended owing to possible extravasation and transient radial nerve palsy. |
| Complete lateral release | ■ The ECRB insertion site spans 1.5 cm of lateral epicondyle.  
■ Débridement of the ECRB tendon is carried up the lateral flare of the epicondyle.  
■ Lateral epicondyle decortication is best done with an abrader and ensures the entire ECRB tendon is released. |
| Access to posterior compartment | ■ Direct lateral portal for visualization  
■ Direct posterior portal as the working portal  
■ Surgeon is seated with arthroscope draping across his or her thighs. The patient’s wrist should be flexed and the dorsum of the hand should be on the surgeon’s thigh. Raising or lowering the bed allows for the elbow to be extended and flexed, respectively. |
| Iatrogenic lateral collateral ligament complex injury | ■ The surgeon should not decorticate posterior to the lateral epicondyle.  
■ A 30-degree scope prevents injury to the lateral collateral ligament because it does not allow good posterior visualization. |

POSTOPERATIVE CARE
■ Postoperatively the patient is placed into a sling for comfort.  
■ Range of motion is begun immediately with the assistance of a physical therapist.  
■ Rehabilitation goals include edema control with icing, full active range of motion, gradual strengthening, hand exercises, and ergonomic education.  
■ Patients return to full activity as tolerated.  
■ Soldiers undergoing this technique were able to return to full, unrestricted active duty within an average of 6 days (less than 28 days).7,11

OUTCOMES
■ Cadaveric and anatomic studies have shown that elbow arthroscopy and ECRB release is safe, reliable, and reproducible.7,11
■ Two clinical series confirm the long-term subjective and functional improvement, as well as faster return to activity, with arthroscopic treatment.  
■ In 16 patients who underwent an arthroscopic release, the average return time to unrestricted work was 6 days, with no complications or need for further surgery.11
■ In 2000, we evaluated the clinical results of arthroscopic lateral elbow release. Patients rated 95% of the elbows to be “much better” or “better.” Sixty-two percent of the patients were completely pain-free at an average of 2.8 years of follow-up.2
■ Results from open releases have shown time to return to activity as long as 3 to 6 months, with one study reporting that 60% of patients could not return to high-demand sports participation postoperatively.  
■ Arthroscopy, unlike open and percutaneous procedures, gives the surgeon the distinct ability to address concurrent intra-articular pathology.  
■ This may be particularly important because we have found rates of intra-articular pathology from 11% to 18% in our series, and some have reported rates as high as 40%.9

COMPLICATIONS
■ Transient nerve palsy versus direct nerve injury14  
■ Superficial infection  
■ Iatrogenic lateral collateral ligament injury with posterolateral instability7  
■ Hematoma

REFERENCES
DEFINITION

- The hip is increasingly recognized as a source of pain owing to heightened awareness of pathologies, recent research, enhanced imaging techniques, and greater popularity of hip arthroscopy as a diagnostic and therapeutic tool.
- Hip arthroscopy first was performed on a cadaver in the 1930s by Burman, but it was not performed regularly until the 1980s, serving mostly as a tool for diagnosis and simple treatments, such as loose body removal, synovial biopsy, and partial labrectomy.
- With improvements in instrumentation, indications for hip arthroscopy have expanded, because surgeons now are able to do more in the hip with decreased risk of iatrogenic injury. Further, enhanced imaging techniques have allowed noninvasive diagnosis, and research has led to increased understanding of hip pathologies, furthering interest in this procedure.
- Hip arthroscopy can be performed in the central compartment (femoroacetabular joint) and peripheral compartment (along the femoral neck), which also has expanded the indications and success of hip arthroscopy, propagating the popularity of this procedure.

ANATOMY

- The hip joint is a multiaxial ball-and-socket type of synovial joint in which the head of the femur (ball) articulates with the acetabulum (socket) of the hip.
- Articular cartilage covers the head of the femur and acetabulum but is not present at the fovea.
  - The articular cartilage of the femoral head and acetabulum is relatively thin compared with that of the knee.
  - The acetabular labrum is a triangular fibrocartilage that attaches to the rim of the acetabulum at the articular cartilage edge, except at the inferiormost region of the acetabulum, where the transverse acetabular ligament extends the acetabular rim.
- The hip joint is enclosed by a capsule that is formed by an external fibrous layer and internal synovial membrane, and attaches directly to the bony acetabular rim.
- The fibrous layer consists of the iliofemoral, pubofemoral, and ischiofemoral ligaments, which anchor the head of the femur into the acetabulum (FIG 1A).
- The ligamentum teres is extracapsular and travels from the central acetabulum to the foveal portion of the femoral head (FIG 1A).
- The major arteries supplying the hip joint include the medial and lateral circumflex femoral arteries, which branch to provide the retinacular arteries that supply the head and neck of the femur (FIG 1D).
- The artery to the head of the femur also supplies blood and transverses the ligament of the head of the femur (ie, the ligamentum teres).
- The labrum has a relatively low healing potential, because vessels penetrate only the outermost layer of the capsular surface.
  - Pertinent extra-articular neurovascular structures near the hip joint include the lateral femoral cutaneous nerve, femoral nerve, superior gluteal nerve, sciatic nerve, and the ascending branch of the lateral circumflex femoral artery.
  - The lateral femoral cutaneous nerve, formed from the posterior divisions of L2 and L3 nerve roots, supplies the skin sensation of the lateral thigh. It travels from the pelvis just distal and medial to the anterosuperior iliac spine (ASIS) and divides into more than three branches distal to the ASIS.
  - The femoral nerve and artery run together with the femoral vein. They pass under the inguinal ligament midway between the ASIS and the pubic symphysis, with the nerve being most lateral and the vein most medial but being mostly superficial at the level of the hip.
  - The femoral nerve is 3.2 cm from the anterior hip portal, but slightly closer at the level of the capsule.
  - The superior gluteal nerve, formed from the posterior divisions of L4, L5, and S1, passes posterior and lateral to the obturator internus and piriformis muscles, then between the gluteus medius and minimus muscles approximately 4 cm proximal to the hip joint.
- The sciatic nerve, formed when nerves from L4 to S3 come together, passes anterior and inferior to the piriformis and posterior to the deep hip external rotators to supply the hamstrings and lower leg, foot, and ankle.
  - The sciatic nerve is 2.9 cm from the posterior hip arthroscopy portal, but is closest at the level of the capsule.
  - Externally rotating or flexing the hip prior to making the posterior portal brings the nerve dangerously close to the arthroscope.
  - The lateral femoral circumflex artery is a branch of the femoral artery that, along with the medial circumflex artery, forms a vascular ring about the neck of the femur, providing arteriole branches to supply the femoral head (FIG 1D).
  - The lateral femoral circumflex artery is 3.7 cm inferior to the anterior arthroscopy portal; it is much closer at the level of the capsular entry of the arthroscope.

PATHOGENESIS

- Loose bodies can be ossified or nonossified, and can either appear after traumatic hip injury or be associated with conditions such as osteochondritis dissecans and synovial chondromatosis.
- Labral tear often results from hyperextension or external rotation of the hip and is more likely with hip dysplasia.
- Chondral (articular cartilage) damage can result from dislocation or subluxation of the hip or direct impact onto the hip and is associated with labral tears in more than half the cases.
  - Femoroacetabular impingement is a major cause of labral tears and chondral damage.
  - It usually occurs when there is loss of femoral head-neck offset (CAM impingement), excessive acetabular coverage (eg, osteophytes, retroversion, overcorrection with pelvic
osteotomy, protrusio acetabuli, or otto pelvis) (pincer impingement), or both.
- The femoral head–neck junction abuts the acetabulum and labrum, resulting in tearing of the labrum, delamination of the articular cartilage, synovitis, and, eventually, arthritis.
- Ligamentum teres pathology may be due to ligament hypertrophy or partial or complete tearing and may be the result of trauma or degenerative joint disease (DJD).
- Ligamentum hypertrophy or tearing may result in pain as a result of catching of a thickened or torn edge between the joint surfaces.
- DJD may be associated with loose bodies, labrum tears, chondral damage, ligamentum teres pathology, and synovitis.
- Avascular necrosis of the femoral head is primarily idiopathic, but can be associated with corticosteroid use, alcohol consumption, fracture, and deep sea diving (caisson disease), among others.
- Synovial diseases such as pigmented villonodular synovitis (PVNS), synovial chondromatosis, inflammatory arthritis, and osteochondromatosis can be sources of hip pain and joint damage.

**NATURAL HISTORY**
- The natural history of most pathologies about the hip has not been studied; much of the purported natural history is conjecture, therefore.
- Removal of loose bodies alleviates mechanical symptoms and reduces articular cartilage damage.
- Labral tears and chondral lesions that are debrided may result in degenerative arthritis.
- Untreated femoroacetabular impingement may result in degenerative arthritis.
- It has been proposed, but not proved, that labral repair or surgery for femoroacetabular impingement may lower the risk of developing DJD or slow the rate of degeneration.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The patient history should include an investigation of the quality and location of pain, timing and precipitating cause of symptoms, and any referred pain.
- Patients with intra-articular pathology may have difficulty with torsional or twisting activities, discomfort with prolonged hip flexion (eg, sitting), pain or catching from flexion to extension (eg, rising from a seated position), and greater difficulty on inclines than on level surfaces.²
- Intra-articular pathology may be associated with groin pain extending to the knee and mechanical symptoms such as popping, locking, or restricted range of motion (ROM).³
  - The source of intra-articular pathology should be investigated in patients with continuous hip pain for longer than 4 weeks.
- Physical examination methods are summarized later.
  - It is important to follow a systemic approach to examination that includes inspection, palpation, ROM, strength, and special tests.²⁶
- Intra-articular pathologies do not have palpable areas of tenderness, although compensation for longstanding intra-articular problems may result in tenderness of muscles or bursae.
- Motor strength and neurovascular examinations must be performed for the entire lower extremity.
- It is important to rule out other causes of pain referred to the hip.
  - Spinal pain usually is localized at the posterior buttock and sacroiliac region and may radiate to the lower extremity.
  - Injuries to the sacrum and sacroiliac joint are recognized by a positive gapping or transverse anterior stress test.
  - Abdominal injuries are recognized by basic inspection and palpation of the abdomen for a mass or fascial hernia, which can be evaluated by isometric contraction of the rectus abdominis and obliques.
  - Abdominal muscle injury is recognized by pain during contraction of the rectus abdominis and obliques.
  - Herniography may be used to rule out hernias.
    - Particularly difficult to diagnose is the sports hernia (Gilmore’s groin).
  - Genitourinary tract
    - Injuries to the pelvic area, such as pubic symphysis and intrapelvic problems, are recognized by the gapping/transverse anterior stress test.
- Specific tests for the hip include the following:
  - McCarthy test: distinction of internal hip pathology such as torn acetabular labrum or lateral rim impingement
  - Stinchfield and Fulcrum test: diagnosis of internal derangements, primarily of the anterior portion of the acetabulum
  - Scour test: associated with micro-instability or combined anterior anteverision; acetabular anteverision summation; hyperlaxity; or strain of the iliofemoral ligament
  - Thomas test: tests for flexion contracture. Extension to 0 degrees (in line with the body) without low back motion is normal. Less than full extension without rotating the pelvis or lifting the lower back is consistent with a flexion contracture.
  - Ober test: used to evaluate ilioband tightness. The test is positive when the upper knee remains in the abducted position after the hip is passively extended and abducted, then adducted, with the knee flexed. If, when the hip and knee are allowed to adduct while the hip is held in neutral rotation, the knee adducts past midline, the hip abductors are not tight; whereas if the knee does not reach to midline, then the hip abductors are tight.
  - Ely’s test: if on flexion of the knee the ipsilateral hip also flexes, then the rectus femoris is tight.
  - Trendelenburg test: indicative of hip abductor weakness, and may indicate labrum pathology that affects neuromusculo-propriocceptive function. If the pelvis (iliac crest or posterior superior iliac spine) of the ipsilateral hip of the leg that is lifted elevates from the neutral standing position, this is normal. If the pelvis drops below the contralateral pelvis or from the starting position (ie, iliac crest/posterior superior iliac spine) this is considered a positive Trendelenburg sign and indicative of hip abductor weakness of the muscles on the extremity standing on the ground. If the pelvis stays level, then this is indicative of mild weakness and recorded as level.
  - Patrick’s test (FABER test): indicative of sacroiliac abnormalities or iliopsoas spasm. Pain may be felt with downward stress on the flexed knee. Pain in the posterior pelvis may be considered a positive finding that indicates the pain is coming from the sacroiliac joint.
  - Labral stress test: indicative of labral tear. The patient will note groin pain or a click in a consistent position as the hip is being rotated.
  - Piriformis test: pain in the lateral hip or buttock reproduced by this maneuver is consistent with pain from the piriformis.
  - Impingement test: pain in the groin is a positive test and is consistent with femoroacetabular impingement.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Routine anteroposterior (AP) and lateral (usually cross-table lateral) radiographs should be obtained in all patients with hip pain to evaluate variations in bony architecture and visualization of areas that may present with hip pain such as the pubic symphysis, sacrum, sacroiliac joints, ilium, and ischium.
- Radiographs help exclude degenerative joint changes, osteonecrosis, loose bodies, stress fractures, or other osseous pathology, and help assess for acetabular dysplasia and femoral neck abnormalities (hump or cam lesion) and femoroacetabular impingement (FIG 2A,B).
- Bone scan or radionuclide imaging is sensitive in detecting fractures, arthritis, neoplasm, infections, and vascular abnormalities, but has low specificity and poor anatomic resolution.
- MRI is used to detect stress fractures of the femoral neck and to identify sources of hip pain such as osteonecrosis, pigmented villonodular synovitis, synovial chondromatosis, osteochondromas, and other intra-articular pathology.
- MRI arthrography can increase the ability to diagnose and describe labral pathology and articular cartilage loss (FIG 2C).
- MRI combined with the use of intra-articular local anesthetic with gadolinium is used to assess pain relief and provide evidence that intra-articular pathology may be causing pain.
- CT, MRI, and occasionally radioisotope imaging typically are required to help diagnose labral tears, hip instability, iliopsoas tendinitis, inflammatory arthritis, early avascular necrosis, occult fractures, psoas abscess, tumor, upper lumbar radiculopathy, or vascular abnormalities.
- CT scan can be useful to measure ante- and retroversion of the femoral neck and acetabulum, to show the size and shape of the acetabulum and femoral head and neck, to elucidate bony architecture, to confirm concentric reduction after hip dislocation, and to rule out loose bodies.
- Ultrasound is a nonionizing way of evaluating intra-articular effusions and soft tissue swelling.
- Iliopsoas bursography is the choice imaging modality to detect iliopsoas bursitis and internal snapping hip.
- Iliopsoas bursitis and internal snapping hip may be evaluated with real-time dynamic ultrasound.
- Three-dimensional CT is used to assess bony deformities, including oseophytes of the acetabulum and femoral neck bony lesions, which may cause impingement (FIG 2D).

**DIFFERENTIAL DIAGNOSIS**
- Labral tear
- Chondral delamination or degeneration
- Dysplasia
- Femoroacetabular impingement
- Synovitis
- Synovial chondromatosis
- Synovial osteochondromatosis
- Loose bodies
- Ligamentum teres tear
- Ligamentum teres hypertrophy
- Sepsis of the hip
- Arthritis of the hip
- Hip dislocation or subluxation
- Avascular necrosis of the femoral head
- Sacroiliac joint pathology, including ankylosing spondylitis
- Trochanteric bursitis
- Athletic pubalgia
- Femur, pelvic, or acetabular fractures or stress fractures
- Myotendinous strains
- Piriformis syndrome
- Myositis ossification
- Neurologic irritation
- Hamstring syndrome
- Iliotibial band syndrome
- Iliopsoas tendon problems (eg, snapping and tendinitis)
- Tendinitis
- Tendon injuries (iliopsoas, piriformis, rectus, hamstring, or adductor)
- Benign tumors (eg, osteoid osteoma, osteochondroma)
- Occult hernia
- Lumbar spine (mechanical pain and herniated discs)
- Abdomen
- Osteitis pubis

**FIG 2** • AP radiographs of the pelvis (A) and lateral hip (B) of a patient with concomitant developmental dysplasia of the hip and degenerative joint disease. C. MRI arthrogram of patient with femoroacetabular impingement. Note the subchondral edema and chondral lesion. D. Three-dimensional CT scan showing cam impingement with non-union of a superior acetabular stress fracture in a 32-year-old athletic man.
NONOPERATIVE MANAGEMENT
- Conservative therapy includes rest, ambulatory support, nonsteroidal anti-inflammatory drugs, and physical therapy.
- Most pathologies about the hip usually are treated initially with conservative management, including relative rest, NSAIDs, and rehabilitation. Occasionally, use of ambulatory assist devices may be needed.
- However, several intra-articular pathologies do not resolve or heal with nonoperative management, including labral tears, loose bodies, articular cartilage lesions, and femoroacetabular impingement.

SURGICAL MANAGEMENT
- Proper patient selection is essential for a successful surgical outcome.
- Arthroscopy is most successful for patients with recent, symptomatic intra-articular hip joint pathology, particularly those with mechanical symptoms, and minimal arthritic changes.
- Arthroscopy should be considered if hip pain is persistent, is reproducible on physical examination, and does not respond to conservative treatment.
- Pain relief with intra-articular injection of local anesthetic also is a good predictive sign for success.
- Indications for arthroscopy include loose bodies, foreign objects, labral tears, chondral injuries, synovial disease, femoroacetabular impingement, mild degenerative disease with mechanical symptoms, osteonecrosis of femoral head, osteochondritis dissecans, ruptured ligamentum teres, snapping hip syndrome, impinging osteophytes, adhesive capsulitis, iliopsoas tendon release, iliopsoas bursitis, trochanteric bursa, iliobial band resection, crystalline hip arthropathy, hip instability, joint sepsis, osteoid osteoma, osteochondroma, and unresolved hip pain.
- ROM should be evaluated before arthroscopy to determine the presence of contractures.
- Arthroscopy can be a means to delay total arthroplasty for DJD.
- Contraindications include systemic illness, open wounds, soft tissue disorders, poor bone quality (ie, unable to withstand traction), non-progressing avascular necrosis of the femoral head, arthrofibrosis or capsular constriction, and ankylosis of the hip.
- Severe obesity is a relative contraindication that may be circumvented with extra-length instruments.
- Indications for labrectomy include relief of pain with intra-articular injection of anesthetics, no pain relief with physical therapy or nonsteroidal anti-inflammatory drugs, missed time due to delayed diagnosis, and symptoms for longer than 4 weeks.
- Arthroscopy for DJD should be considered for younger patients with mild-moderate disease who present with mechanical symptoms and no deformity.
- Microfracture is indicated for grade IV chondral lesions with healthy surrounding articular surface and intact subchondral bone.
- Treatment of sepsis involves drainage, lavage, débridement, and postoperative antibiotics, and requires early diagnosis.
- Sepsis in the setting of joint arthroplasty requires prompt arthroscopic débridement, well-fixed components, a sensitive microorganism, and patient tolerance to and compliance with antibiotic therapy.15

Preoperative Planning
- A physical examination should be completed and radiographs and other imaging reviewed before arthroscopy.
- A three-dimensional CT scan may be obtained to further assess bony abnormalities (see Fig 2D).
- Arthroscopy usually is performed under general anesthesia.
- If epidural anesthesia is used, it also requires adequate motor block to relax muscle tone.
- Typical instrumentation includes a marking pen; no. 11 blade scalpel; 6-inch 17-gauge spinal needles; 60-mL syringe of saline with extension tubing; a Nitanol guidewire; 4.5-, 5.0-, and 5.5-mm cannulas with cannulated and solid obturators; a switching stick; a separate inflow adaptor; and a modified probe.
- Fluid used can be introduced by gravity or a pump.
- Specialized arthroscopy equipment for the hip is available that is extra-long and extra-strong to withstand the lever arm due to the extra length. These instruments include shavers, burrs, biter, probes, curettes, and loose body retrievers.

Positioning
- The patient may be placed in either the supine or lateral decubitus position on a fracture table or attachment that allows for distraction of the hip joint.
- The lateral decubitus position offers the benefit of directing fat away from the operative site.
- The involved hip joint is in neutral rotation, abducted at 10 to 25 degrees, and in neutral flexion-extension (FIG 3A).
- Flexion of the involved hip during distraction and portal placement increases the risk of injury to the sciatic nerve.
- The nonoperative hip also is abducted and is placed under slight traction to stabilize the patient and allow placement of the image intensifier between the legs and directed over the operative hip.
- A heavily padded perineal post is placed against the pubic ramus and ischial tuberosity, but lateralized against the medial thigh of the operative hip, with care taken to protect perineal structures (FIG 3B).
- It is important to lateralize the traction vector such that it is parallel to the femoral neck to minimize risk of pressure neuropraxia to the pudendal nerve, and to optimize distraction of the joint.
- The surgeon, assistant, and scrub nurse stand on the operative side, facing the arthroscopic monitor on the opposite side of the patient (FIG 3C, D).
- The fluoroscopy monitor is placed at the foot of the fracture table.

Approach
- Portal placement and arthroscopic technique do not differ between the supine and lateral decubitus positions.
- Hip arthroscopy usually is performed through three portals: anterolateral, anterior, and posterolateral.
- A shortened bridge can accommodate the use of 4.5-, 5.0-, and 5.5-mm cannulas.
- Although a 5.0-mm cannula is used for initial entry of the arthroscope, a 4.5-mm cannula permits interchange of the inflow, arthroscope, and instruments, and a 5.5-mm cannula allows entry of larger instruments (eg, shaver blades).
A 30-degree videoarticulated arthroscope provides best visualization of the central portion of the acetabulum, the femoral head, and the superior aspect of the acetabular fossa.

A 70-degree videoarthroscope provides optimal visualization of the periphery of the joint, the acetabular labrum, and the inferior aspect of the acetabular fossa.

The holmium YAG laser and radiofrequency device are used to ablate tissue and can offer increased maneuverability over shavers.

Extra-length convex and concave curved shaver blades are used to remove tissue around the femoral head.

Fragile, extra-length instruments designed for other arthroscopic procedures should be avoided, because these have a greater tendency to break.

**HIP DISTRACTION**

- The patient is prepared with chlorhexidine (Hibiclens) or povidone-iodine (Betadine).
- Traction is applied to distract the joint 7 to 10 mm.
- A tensiometer may be used to monitor traction force (typically 25 to 50 pounds).
- Traction time should be monitored. It is important to limit the time to less than 2 hours to prevent complications such as compression of the pudendal nerve or injury to other nerves.

- The spinal needle is introduced under fluoroscopy at the anterolateral position into the joint capsule to equilibrate the space with the ambient pressure (TECH FIG 1A,B).
- Pressure in the joint may be equilibrated with air or saline (TECH FIG 1C).
- Care should be taken to avoid penetrating the labrum and articular surfaces with the spinal needle.
Portals are established by penetrating the skin with a 6-inch 17-gauge spinal needle and positioning the needle into the respective joint space.

The trocar of the spinal needle is removed and a Nitanol guidewire (Smith & Nephew Endoscopy, Andover, MA) is run through the needle into the joint space (TECH FIG 2A,B).

The needle is removed.

A long cannula sheath with cannulated trocar is advanced over the guidewire into the joint space (TECH FIG 2C–E).

The cannulated obturator should be kept off the femoral head to avoid articu lar damage.

It is important to avoid cannula removal and reintroduction, because this may damage cartilage.

It may be necessary to release the capsule with an arthroscopic knife.

The weight-bearing portion of the femoral head is visualized by using the arthroscope in all three central compartment portals with the 70- and 30-degree lenses or by internally and externally rotating the hip intraoperatively.

The fossa and ligamentum teres typically are visualized from all three portals, particularly using the 30-degree lens.
ANTEROLATERAL PORTAL

- The anterolateral portal is created first because it is the safest, being the most distant from and posing least risk of injury to the femoral and sciatic neurovascular structures.
- The portal penetrates the gluteus medius muscle and is positioned directly over the superior aspect of the greater trochanter at its anterior margin to enter the lateral capsule at its anterior margin (TECH FIG 3).
- When creating the anterolateral portal, it is important to introduce the spinal needle in the coronal plane by keeping it parallel to the floor (see Tech Fig 2A).
- As the cannula is positioned into the intra-articular space, care should be taken to avoid damage to the labrum or articular surfaces.
- The portal provides visualization of most of the acetabular cartilage, labrum, and weight-bearing femoral head within the central compartment, as well as visualization of the peripheral compartment, such as the non-weight-bearing femoral head, the anterior neck, the anterior intrinsic capsular folds, and the synovial tissues beneath the zona orbicularis and the anterior labrum.
- The superior gluteal nerve is the closest neurovascular structure and runs 4.4 cm posterior to the portal.

ANTERIOR PORTAL

- I prefer to establish the anterior portal after the anterolateral portal, although some prefer to establish the anterior portal first.
- Arthroscopic visualization from the anterolateral portal and fluoroscopy facilitate correct portal placement, helping to avoid damage to the labrum or articular surfaces.
- The anterior portal enters at the junction of a line drawn distally from the anterosuperior iliac spine and a transverse line across the superior margin of the greater trochanter (TECH FIG 4A).
- The portal penetrates the sartorius and rectus femoris muscles as it is directed 45 degrees cephalad and 30 degrees medially to enter the anterior capsule (TECH FIG 4B,C).
- As the cannulated obturator enters the joint space, it should be kept off the articular surface and directed underneath the acetabular labrum.
- The portal allows visualization of the anterior femoral neck, the anterior aspect of the joint, the superior retinacular fold, the ligamentum teres, and the lateral labrum.

TECH FIG 3 • The anterolateral portal starts just anterior to the superior aspect of the greater trochanter and pierces the gluteus medius muscle.

TECH FIG 4 • The anterior portal usually is the second portal made and is created under arthroscopic visualization with a 70-degree arthroscopic lens from the anterolateral portal and fluoroscopic visualization. A. Introduction of the spinal needle using the junction of the superior aspect of the greater trochanter and a line drawn inferiorly from the anterior superior iliac spine (ASIS) as the starting point. B. Fluoroscopic view of the arthroscope in the anterolateral portal and spinal needle being introduced from the anterior portal. (continued)
Care should be taken to minimize injury to branches of the lateral femoral cutaneous nerve by directing movement medially, avoiding deep cuts at the entry site, not using vigorous instrumentation, and using a 70-degree arthroscope at the anterolateral portal to guide entry (TECH FIG 4D).

- The femoral nerve is 3.2 cm medial and runs tangential to the portal.
- The ascending branch of the lateral femoral circumflex artery is 3.7 cm inferior to the portal, but terminal branches may be within millimeters of the portal at the capsular level.

POSTEROLATERAL PORTAL

- The posterolateral portal is established after the anterior portal (TECH FIG 5A).
- Arthroscopic visualization and fluoroscopy are used to guide portal placement.
- The portal penetrates the gluteus medius and minimus muscles and is directed over the superior aspect of the greater trochanter at its posterior border to enter the lateral capsule at its posterior margin (TECH FIG 5B).
- The portal is superior and anterior to the piriformis.
- The portal allows visualization of the posterior aspect of the femoral head, the posterior labrum, the posterior capsule, and the inferior edge of the ischiofemoral ligament (TECH FIG 5C).
- The sciatic nerve is 2.9 cm posterior to the portal at the level of the capsule.
  - It is important to maintain the leg in neutral rotation and extension, and to introduce the spinal needle horizontally to avoid injury to the sciatic nerve.

TECH FIG 4 • (continued) C. Schematic depiction of the location of the portal adjacent to the branches of the lateral femoral cutaneous nerve, penetrating the sartorius and rectus femoris muscles. D. Care is taken only to cut the skin when making the anterior portal, to help reduce the risk of laceration of the lateral femoral cutaneous nerve.

TECH FIG 5 • Posterolateral portal. The posterolateral portal usually is the last central portal made, although it can be made before the anterior portal. A. How the posterolateral portal is made, relative to the other portals. (continued)
**TECH FIG 5 • (continued)**

**B.** The posterolateral portal proceeds through the gluteus medius and minimus muscles. Note its relation to the superior gluteal nerve. **C.** View of obturators in all three central compartment portals to allow for complete central compartment hip arthroscopy. Both a 30- and a 70-degree lens are used in all the portals to allow for full visualization of the femoroacetabular joint to perform a complete hip arthroscopy of the central compartment.

---

**DISTAL ANTEROLATERAL PORTAL**

- To access the peripheral compartment–femoral neck region, two portals are used after traction is removed from the extremity.
- Peripheral compartment arthroscopy can be done in hip flexion to relax the anterior capsule or in neutral flexion extension.
- The anterolateral portal is used as one portal.
- A distal anterolateral portal is established 3 to 5 cm distal to the anterolateral portal, just anterior to the lateral aspect of the proximal femoral shaft and neck (**TECH FIG 6**).
- Fluoroscopy is used to guide portal placement.
- The portal penetrates the gluteus medius muscle and upper vastus lateralis.
- The spinal needle should enter the peripheral compartment laterally. The guidewire is brought through the spinal needle and can be gently advanced to the medial capsule—the easy passage until the medial capsule is reached helps confirm that one is in the peripheral compartment.
- The skin incision is made, and the trocar and the sheath are passed over the guidewire.
- The sheath and guidewire are exchanged for the arthroscope or instrumentation.
- Arthroscopy and fluoroscopy can be used together to perform surgery in the peripheral compartment.

**TECH FIG 6 •** Distal anterolateral portal. The distal anterolateral portal allows a second portal for peripheral compartment arthroscopy. This portal is 2.5 to 5 cm distal to the anterolateral portal (**A**). This example shows the hip in neutral flexion–extension, which makes it easier to perform a chielectomy or osteoplasty for cam-type femoroacetabular impingement to maintain orientation while using fluoroscopy to assist with the procedure (**B**). Alternatively, the hip can be flexed, relaxing the anterior capsule, making entry into the joint easier.
PEARLS AND PITFALLS

| Patient selection | • A careful patient history, physical examination, and appropriate imaging should be performed. |
| • Distinguish intra-articular conditions that may require surgery for extra-articular problems that may only require conservative treatment. |
| • Patients should have clear expectations of outcomes. |
| Hip distraction | • Distract the hip with as much force as necessary to safely introduce instruments, typically 8 to 10 mm. |
| • Limit traction time to 2 hours or take a traction break if it is necessary to exceed this time. |
| • Too little traction may result in injury to the articular surfaces. |
| • Too much traction can result in nerve injury or injury to the perineum, knee, foot, or ankle. |
| Patient positioning | • Obtain the correct vector of joint distraction with minimal force necessary to distract the joint. |
| • The perineal post should be adequately padded and lateraledized against the involved hip. |
| Portal placement | • Proper placement of the anterolateral portal is key to successful placement of other portals. |
| • It is important to avoid damaging the labrum or articular surfaces with either the spinal needle or cannula introduction. |
| • Use inflow from the secondary portal to improve fluid dynamics or use a pump. |
| • Use both 30- and 70-degree cannulas in each portal. |
| • Use specialized hip arthroscopy instruments and metal cannulas to reduce risk of instrument breakage and allow proper technique. |
| • Avoid inserting the cannula multiple times to reduce fluid extravasation and the risk of damage to labrum, cartilage, and neurovascular structures. |
| • Maintain systolic blood pressure below 100 mm Hg and use a radiofrequency device to minimize bleeding. |

POSTOPERATIVE CARE

• Traction is released.
• Long-acting local anesthetic is injected into the joint.
• The portals are sutured, and a sterile dressing is applied to the wounds.
• Arthroscopy is an outpatient procedure, and the patient typically leaves recovery after 1 to 3 hours.
• If arthroscopy does not involve bony recontouring of the femoral neck, labral repair, or microfracture of the articular surfaces, then the patient is allowed to walk immediately, although weight bearing should be limited by crutches for 3 to 7 days or until gait pattern is normalized.
• Rehabilitation should take into consideration soft tissue healing constraints, control of swelling and pain, early ROM, limitations on weight bearing, early initiation of muscle activity and neuromuscular control, progressive lower extremity strengthening and proprioceptive retraining, cardiovascular training, and sport-specific training.
• Swelling and pain are controlled by ice and non-aspirin non-steroidal anti-inflammatory drugs.
• The dressing is removed on the first or second postoperative day, and the wound is covered with adhesive bandages.
• Portal sutures are removed a few days after surgery.
• Patients who undergo labrum repairs on the anterior superior region and capsulorraphy should follow specific ROM and weight bearing guidelines.
• Patients who undergo osteoplasty should limit impact activities that increase the risk of femoral neck fracture during the initial several weeks.
• Patients who undergo microfracture should adhere to 8 to 10 weeks of protected weight bearing on crutches.

OUTCOMES

• Record functional and prosthetic survivorship data, as applicable.
• Loose bodies are the clearest indication for arthroscopy, resulting in less morbidity and faster recovery than open surgery.8
• Labral débridement has been shown to result in successful outcomes in 68% to 82% of cases, with positive outcomes associated with isolated tears and poorer prognosis associated with arthritis.2,10,27
• Débridement of ligamentum teres, like labral débridement, has shown best results when lesions are isolated and without associated acetabular fracture or significant osteochondral defect of either the acetabulum or femoral head.
• Treatment of hip DJD by arthroscopy has shown unpredictable results, with a range of 34% to 60% of patients reporting improvement of symptoms after arthroscopic débridement for DJD.11,31
• One study reported that 86% of patients treated for chondral lesions by microfracture showed a successful response at 2-year follow-up.1
• Arthroscopic synovectomy is palliative, and success is based on the integrity of the articular cartilage.
• Treatment of femoroacetabular impingement has shown better outcomes when there is less DJD.
• Treatment of AVN is controversial—the results are better when the articular surface is not disrupted or when treating mechanical symptoms.
• O’Leary23 reported 40% of patients improved at 30-month follow-up.
• More specifics are provided in the chapters describing specific techniques for the different processes treated about the hip.

COMPLICATIONS

• Traction neurapraxia
• Direct trauma to pudendal, lateral femoral cutaneous, femoral, and sciatic nerves
• Iatrogenic labral and chondral damage
• Fluid extravasation
• Vaginal tear
• Pressure necrosis to scrotum, labia and perineum, and foot
• Labia and perineum hematoma
Knee ligament injury
Ankle fracture
Femoral head avascular necrosis
Fracture of femoral neck
Instrument breakage
Portal hematoma and bleeding

REFERENCES
DEFINITION
- Soft tissue pathology of the hip includes labral tears, articular damage, and lesions of the ligamentum teres, all of which share several common features.
- The clinical presentations may be indistinguishable, and these lesions often coexist. They represent significant causes of disabling hip pain that can be elusive to clinical detection.
- The diagnosis sometimes is based just on maintaining an index of suspicion. Often these lesions have gone undiagnosed and untreated, with the patient simply resigned to living within the constraints of their symptoms.

ANATOMY
- The horseshoe or lunate articular surface of the acetabulum surrounds the acetabular fossa (FIG 1).
- The articular surface of the femoral head forms about two thirds of the sphere, with an indentation medially where the ligamentum teres attaches at the fovea capitis.
- The diameter of the femoral neck normally is 65% of the diameter of the femoral head, allowing clearance of the acetabulum during range of motion (ROM).
- The fibrocartilaginous labrum is triangular in cross section, forming a rim around the articular surface of the acetabulum.
- Inferiorly, it is contiguous with the transverse acetabular ligament, which traverses the inferior aspect of the fossa. Its morphology and size can be quite variable, especially anterior and superior.
- The shape of the posterior labrum is the most consistent and least often damaged landmark, representing a useful reference in the arthroscopic assessment of labral pathology.
- Unlike the shoulder, there is no capsulolabral complex; the capsule attaches directly to the acetabulum separate from the labrum. Thus, acetabular labral pathology is not as synonymous with instability as that of the glenoid.
- Konrath et al17 have shown that the labrum has minimal mechanical properties for distributing forces across the acetabular surface. Similarly, Ferguson13 has demonstrated that the labrum has minimal mechanical properties for stabilizing the joint, but its hydraulic seal is important.
- The ligamentum teres has a serpentine course from its acetabular attachment in the posterior fossa to the fovea capitis of the femoral head. Its precise function remains an enigma.

FIG 1 • Macroscopic anatomy of the hip joint. (Courtesy of Delilah Cohn.)
In childhood, its vessel contributes to the blood supply of the femoral head. Its redundant nature implies that it contributes little to joint stability, but it may have nociceptive and proprioceptive functions.

Gray and Villar have postulated that its windshield wiper effect during ROM may facilitate joint lubrication. Its dimensions are variable, and sometimes it is absent in adulthood.

**PATHOGENESIS**

- The etiologies of soft tissue lesions in the hip are numerous and variable. Breakdown may result from supraphysiologic loads on normal tissue, physiologic loads on abnormal tissue, or, commonly, mildly supraphysiologic loads on mildly abnormal tissue.
- Supraphysiologic loads may be the result of macrotrauma or repetitive microtrauma.
- Athletes are especially prone to pushing their bodies beyond the physiologic limits where breakdown occurs.
- Once this point has been passed, reversal of the damage often is incomplete, even with surgical intervention. Variable joint morphology often is a contributing factor.
- Labral tears can occur from compression, commonly associated with impingement; traction associated with excessive translation of the femoral head; and shear forces, typically associated with acetabular dysplasia.
- Articular damage can be caused by acute trauma or degenerative disease. A propensity for acute articular fracture has been identified in physically fit young men, resulting from a direct lateral blow to the trochanter.
- There is little adipose tissue over the trochanter to cushion the blow; and with high bone density fracture does not occur, so the force is delivered directly to the joint surface.
- Lesions of the ligamentum teres can occur from acute trauma or degeneration.
- The ligament is most taut with adduction and external rotation, but acute rupture has been identified with a variety of mechanisms.
- Deterioration of the ligament occurs with degenerative disease, and the ligament is sometimes hypertrophied, making it more susceptible to degenerate rupture.
- Femoroacetabular impingement (both pincer and cam type) has been recognized as a causative factor in the development of soft tissue joint damage. It is the soft tissue damage that then becomes symptomatic, necessitating treatment.
- Pincer impingement is associated primarily with labral pathology due to excessive compression and then secondary development of articular breakdown (FIG 2A).
- Cam impingement is associated with selective articular delamination of the anterolateral acetabulum with a variable amount of associated labral pathology (FIG 2B).
- Dysplasia is associated with breakdown of the labrum, articular surface, and ligamentum teres.
- The labrum often is enlarged, with more weight-bearing responsibility, making it susceptible to a breakdown from shear forces. It also can become inverted within the joint and susceptible to deterioration.
- The reduced surface area of the acetabulum results in increased contact forces, which may exceed the structural integrity of the articular cartilage.
- Hypertrophy of the ligamentum teres occurs in association with dysplasia, and the hypertrophied ligament is more susceptible to degenerative rupture.

**NATURAL HISTORY**

- The natural history of these soft tissue lesions is variable. Some conditions deteriorate quickly, whereas others may remain stable for a protracted period of time, and some become asymptomatic.

---

**FIG 2**

A. Pincer impingement: mechanism of labral breakdown. B. Cam impingement: mechanism of articular delamination.
Labral degeneration has been observed as an unavoidable consequence of age and is found to be uniformly present in persons over 70 years of age.\textsuperscript{18} Abnormal hip morphology, including impingement and dysplasia, may be found even in absence of joint pathology. When symptomatic soft tissue pathology occurs, it is important to assess for predisposing morphology. Some conditions may remain stable for an indefinite period; however, progressive worsening of symptoms usually dictates more proactive intervention.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Examination of the hip joint is fairly straightforward.\textsuperscript{3} Much of the assessment revolves around ruling out other problems. Patients with chronic hip joint pathology will start to develop other conditions secondarily as they compensate for the joint.
- The secondary conditions, such as gluteal pain or trochanteric bursitis, may be more evident, obscuring the underlying diagnosis. In addition, other conditions such as lumbar spine disease may coexist with hip joint disease.
- There is a significant correlation between hip joint pathology and athletic pubalgia in athletes.
- Increased pelvic motion compensates for restricted hip motion, placing more stress on the pelvic stabilizers and resulting in the soft tissue breakdown characterized by athletic pubalgia.
- The history of injury is variable, with some patients describing a major traumatic event. Others may recount an acute episode such as twisting. In these circumstances, however, the clinician should look closely for predisposing factors, because a healthy joint should be able to withstand these forces.
- Some patients simply describe the insidious or gradual onset of symptoms, further indicative of underlying disease.
- A history of a significant traumatic event indicates a more favorable prognosis of a potentially correctable problem.
- Similarly, mechanical symptoms such as sharp stabbing pain, catching, or locking are favorable indicators for surgical intervention.
- Simply having pain, with or without activity, is a poorer prognostic indicator for the success of arthroscopy.
- Numerous characteristic features of hip joint symptoms have been identified.\textsuperscript{3}
  - Straight plane activities, including running, often are well tolerated.
  - Pivoting and twisting maneuvers usually are more troublesome.
  - Squatting and prolonged hip flexion such as sitting often will exacerbate hip symptoms.
  - Patients may experience a catching sensation when rising from a seated position.
  - Ascending and descending stairs or inclines is more troublesome than walking on level surfaces.
  - Entering and exiting an automobile is very characteristic for recreating symptoms, because it loads the hip in a flexed position while introducing a torsional component.
  - Dyspareunia due to hip pain is uniformly present in sexually active individuals.
  - Difficulty getting shoes and socks on and off usually indicates restricted motion and more advanced disease.
- Localization of the symptoms starts with an understanding that the L3 nerve root serves as the principal innervation of the hip.
- Symptoms, therefore, are sometimes referred to the L3 dermatome, explaining the presence of medial-sided thigh and knee pain.
  - The C-sign is very characteristic of hip joint pathology.
  - Describing their symptoms, patients will cup their hand in the shape of a C above the greater trochanter, gripping their fingers into the groin.
  - Most patients describe groin or anterolateral pain.
- Posterior pain rarely is indicative of hip joint pathology, but may occasionally be a presenting feature.
- It is important to record ROM in a consistent fashion for comparing sides as well as for comparison on subsequent examination.
- Recording flexion and extension must take into account the contributing components of pelvic and lumbar motion. Rotational motion is different when measured in extension versus flexion.
- The log roll test is the most specific test for hip joint pathology:
  - The leg is rolled back and forth, rotating only the femoral head in relation to the acetabulum and capsule, without tensioning any of the surrounding soft tissue structures.
  - The impingement test generally has been found positive for virtually any irritable hip joint, regardless of the nature of the pathology.
  - The leg is placed in maximal flexion, adduction, and internal rotation.
  - This maneuver is more sensitive for hip joint pathology, but may be uncomfortable even in a healthy hip. Thus, it is important to compare the symptomatic to the asymptomatic side.
  - It also is important to distinguish whether this test recreates the type of symptoms that the patient experiences with activity, more than simply whether or not it is uncomfortable.
  - Abduction with external rotation also can be sensitive for eliciting hip joint symptoms.
  - It may impinge upon posterior lesions or exacerbate anterior symptoms from translation of the femoral head and, thus, is not especially specific for the location or type of intra-articular pathology.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs are important for assessing hip morphology.
- A properly centered anteroposterior pelvis radiograph is essential for assessing the morphology of the hip and comparing the affected to the unaffected side (FIG 3).
- The optimal lateral view has yet to be determined, but a standardized reproducible lateral radiograph of the affected hip should be obtained in every case.
- Radiographs usually are normal with regard to specific findings indicative of soft tissue pathology in the hip.
- The soft tissue disease usually is far advanced before any radiographic indices emerge.
- Thus, it is important to scrutinize the radiographs carefully, assessing for subtle indicators of change.
- For example, slight joint space narrowing usually indicates advanced intra-articular disease, and should be viewed
as a cautious indicator in counseling patients on the role of arthroscopy.

- MRI can be useful for the evaluation of hip pathology.
- Low-resolution studies (eg, open magnets and small scanners) are unreliable at detecting hip joint pathology.
- High-resolution scans (eg, 1.5-Tesla magnet, surface coils) are superior but still present limitations.\(^5\)
  - They are best at detecting labral pathology but generally poor at assessing the articular surface or the status of the ligamentum teres.
  - Caution is necessary in assessing labral lesions, because these have been identified in studies of asymptomatic volunteers and occur uniformly as a consequence of age.
  - Indirect findings often are the most reliable.
  - Evidence of an effusion in a symptomatic hip is highly indicative of joint pathology.
  - Paralabral cysts are pathognomonic of labral damage and subchondral cysts are indicative of associated articular damage.
  - Gadolinium arthrography with MRI (MRA) has a greater sensitivity than MRI, but introduces some risk of overinterpreting pathology.\(^5\)
  - A particular challenge is differentiating a labral tear from a normal labral cleft.
  - Assessment of the patient’s symptomatic response to the anesthetic effect of an intra-articular injection is the most reliable diagnostic feature.
  - The intra-articular injection always should include a long-acting anesthetic (eg, bupivacaine).
  - However, this evaluation depends on the patient being able to perform activities that recreate pain prior to injection so that the same activities can be recreated post-injection to assess the amount of pain relief.
  - CT can be superior to MRI for assessing bony architecture.
  - Three-dimensional reconstructions are especially useful in assessing cam impingement.
  - Bone scans are relatively inexpensive, provide a good skeletal survey tool, and can be helpful in assessing osseous homeostasis around the hip.

**DIFFERENTIAL DIAGNOSIS**

- Hip flexor or adductor strain
- Hernia
- Athletic pubalgia
- Nerve entrapment
- Upper lumbar disc
- Referred from visceral origin (eg, gastrointestinal, genitourinary, gynecologic)

**NONOPERATIVE MANAGEMENT**

- Nonoperative management begins with informing the patient on the nature of the disorder; and education regarding warning signs of progressive damage, especially worsening symptoms.
- Activity modification often is necessary to modulate associated discomfort. This may be temporary while managing the acute phase of an injury, or may be long-term for patients coping with a chronic process.
- Distraction mobilization techniques may reduce discomfort and improve function while optimizing ROM.
- Closed-chain stabilization exercises usually are well tolerated and help to protect the joint.
- Trunk and core strengthening are integral to functional recovery.

**SURGICAL MANAGEMENT**

- Surgical intervention is indicated for mechanical symptoms in the presence of clinically suspected joint pathology.
- Conservative treatment may be appropriate for stable, manageable symptoms. A more proactive approach may be indicated if the symptoms are not manageable or demonstrate progressive worsening with time.
- In selecting patients for surgical management, the most important assessment tools are the history and physical examination.\(^5\)
- Imaging studies are helpful only when interpreted in the context of the overall clinical evaluation.
- The surgeon should not be lured by false-positive interpretations or dissuaded by false-negative results.

**Preoperative Planning**

- Numerous intra-articular hip lesions may have similar clinical presentations.
- Imaging studies may only partly reflect the extent of pathology.
- Recent radiographs should be available for review in addition to any other tests that have been performed.
- Radiographic evidence of joint deterioration can occur within a few months; thus, old radiographs are not useful.
- Findings of progressive joint space loss may contraindicate a planned arthroscopic procedure.
- The patient must be properly informed regarding the suspected nature of the joint pathology and also any comorbid conditions that will not be addressed by the procedure.
- The patient should have reasonable expectations of what can be accomplished and the uncertainty regarding what associated pathology may be encountered.

**Positioning**

- Arthroscopy of the intra-articular (“central”) compartment of the hip requires distraction.
Proper positioning is essential to the safety and efficacy of the procedure. A well-padded perineal post should be secured against the ischium but lateralized against the medial thigh (FIG 4A). This keeps the post away from the pudendal nerve and aids in achieving the optimal vector for distraction. Applying slight counter-traction to the nonoperative leg stabilizes the pelvis and keeps the post from shifting as traction is then applied to the operative leg. The amount of abduction of the operative leg can be variable. Less abduction may be necessary with a varus hip to make it possible to introduce the cannulas above the trochanter but enter the joint underneath the lateral lip of the acetabulum. Neutral rotation during portal placement maintains a consistent relationship between the greater trochanter and the joint. Slight flexion (10 degrees) relaxes the capsule and may facilitate distraction (FIG 4B). Excessive flexion should be avoided, because it can place tension on the sciatic nerve and reduce anterior access to the joint. Most standard fracture tables can accomplish the positioning necessary for hip arthroscopy. Specialized positioning devices are more practical for ambulatory surgery centers. These are more affordable and transportable, adapting to standard OR tables. Arthroscopy of the peripheral compartment is performed with traction released and hip flexed (FIG 4C). Traction is released only after the instruments have been removed from the central compartment. Flexion relaxes the capsule, opening the space within the periphery.

Approach
For the intra-articular (“central”) compartment, three standard portals (anterior, anterolateral, and posterolateral) allow access for virtually all procedures (FIG 5A,B). The lateral two portals usually are the easiest to position, but the anterior portal provides the greatest versatility and access to the medial joint space. Eighty percent of the intra-articular pathology resides in the anterior half of the hip and is accessible from the two anteriormost portals. However, the posterolateral portal is important for routine inspection of the posterior recesses as well as access for posteriorly based lesions and the acetabular fossa. Two portals usually are sufficient for the peripheral compartment, but the positioning is widely variable, depending on the nature and location of the pathology to be addressed (FIG 5C,D).
LABRAL DÉBRIDEMENT

- Most symptomatic labral tears are managed with selective débridement of the damaged portion (TECH FIG 1).
- Emphasis is given to preserving healthy tissue, because removal of normal labrum can lead to poorer results.
- A complete joint survey is performed with thorough inspection and palpation of the labrum, identifying its damaged portion.
- Most labral resection is carried out with a power shaver, debulking the damaged tissue.
- Hand instruments and an arthroscopic knife may aid in this resection.
- It is important to preserve the healthy tissue but create a stable transition zone when completing the débridement.
- A radiofrequency device is especially useful for this because of the limited maneuverability imposed by the architecture of the joint.
- Diseased tissue has an increased water content and responds selectively to the thermal device.
LABRAL REPAIR

- Labral repair is best suited for young patients when it is believed that simple débridement may result in inordinate sacrifice of healthy tissue (TECH FIG 2).
- An optimal pattern is a tear at the articulolabral junction where a large segment of otherwise healthy tissue has been detached.
- Labral function is most dependent on its fluid seal. Thus, the goal of repair is to reapproximate the labrum to the adjacent acetabulum.
- The mechanical properties of the labrum are minimal; therefore, the recreation of a bolster effect such as that in the shoulder is not necessary.

TECH FIG 1 • Arthroscopic view of a right hip from the anterior portal. A. A fragmented labral tear with degeneration within its substance is identified. B. Débridement is initiated with the power shaver. C. A portion of the comminuted labral tear is conservatively stabilized with a radiofrequency probe. D. The damaged portion has been removed, preserving the healthy substance of the labrum.

TECH FIG 2 • A. Sagittal MRA image demonstrates an anterior labral tear (arrow). B. Arthroscopy reveals a traumatic detachment of the anterior labrum (indicated by the probe). C. An anchor has been placed with suture limbs passed in a mattress fashion through the detached labrum. D. The labrum has been reapproximated to the articular edge. E. Viewing the peripheral aspect of the labrum, the suture is seen on its capsular surface, avoiding contact with the articular surface of the femoral head. (Courtesy of J. W. Thomas Byrd, MD.)
An anchor should be placed adjacent to the articular edge; it is not necessary for it to be placed on its surface.

The angle created by the articular surface and the bony edge of the acetabulum is more acute than its counterpart in the shoulder, which is created by the articular surface and bony face of the glenoid.

Thus, the direction of anchor entry is more critical, especially to avoid perforation of the articular cartilage. This direction is dictated by the position of the cannula.

The standard portal placements lend themselves well to anchor placement, but if the direction of entry does not seem appropriate, it is best to simply establish another portal with the proper angle for anchor entry.

The anchor is seated adjacent to the articular surface, between it and the detached labrum.

Passage of the suture limbs through the detached labrum can then be accomplished with various suture-passing devices.

It is important that the sutures not be left interposed between the labrum and the articular surface of the femoral head, because this can result in third-body wear on the articular cartilage.

Passing the sutures in a mattress fashion accomplishes reapproximation of the labrum, recreating the seal and avoiding interposed suture in the joint.

CHONDROPLASTY

Chondroplasty of unstable articular fragments is performed in the hip, just as in other joints.

Technical challenges are imposed by the limited instrument maneuverability.

Curved shaver blades aid in navigating the constrained joint architecture (TECH FIG 3A–C).

Radiofrequency devices can further assist in ablating damaged tissue, even within the constraints of the joint. Judicious use is imperative to avoid thermal injury.

Like other joints, microfracture of select grade IV lesions can be performed (TECH FIG 3D–G).

Microfracture is indicated primarily for discrete lesions with healthy surrounding articular surface.

TECH FIG 3 • A. Coronal MRI demonstrates evidence of labral pathology (arrow). B. Arthroscopy reveals extensive tearing of the anterior labrum (*) as well as an adjoining area of grade III articular fragmentation (arrows). C. The labral tear has been resected to a stable rim (arrows), and chondroplasty of the grade III articular damage (*) is being performed. D. Coronal MRI demonstrates evidence of labral pathology (arrow). E. Arthroscopy reveals the labral tear (arrows), but also an area of adjoining grade IV articular loss (*). F. Microfracture of the exposed subchondral bone is performed. G. Occluding the inflow of fluid confirms vascular access through the areas of perforation. (Courtesy of J. W. Thomas Byrd, MD.)
ARTHROSCOPIC REPAIR OF LESIONS OF THE LIGAMENTUM TERES AND PULVINAR

- Disrupted fibers of the ligamentum teres, whether from trauma or degeneration, can be quite painful, creating soft tissue impingement within the joint.
- Associated with this soft tissue impingement, the pulvinar tissue often is hyperplastic or fibrosed and also can create painful symptoms.
- Indiscriminate débridement of the ligamentum teres should be avoided and intact fibers preserved; however, débridement of the disrupted portion can be quite beneficial (TECH FIG 4).

Most of the contents of the acetabular fossa are best accessed from the anterior portal.
- However, a portion of the posterior contents often is best accessed with instrumentation introduced from the posterolateral portal.
- Between these two sites most pathologic processes can be accessed with combinations of straight, curved, and flexible instruments.

TECH FIG 4 • A. Arthroscopic view from the anterolateral portal reveals disruption of the ligamentum teres (*). B. Débridement is begun with a synovial resector introduced from the anterior portal. C. The acetabular attachment of the ligamentum teres in the posterior aspect of the fossa is addressed from the posterolateral portal. (Reprinted with permission from Byrd JWT, Jones KS. Traumatic rupture of the ligamentum teres as a source of hip pain. Arthroscopy 2004;20:385–391.)

PEARLS AND PITFALLS

| Patient selection | Select patients whose clinical circumstances suggest that they could benefit from arthroscopic intervention. Make sure the patient has reasonable expectations of what can be accomplished. Lastly, surgeons should select cases that match their level of experience, which will, of course, evolve over time. |
| Portal placement | Proper portal positioning and placement is essential for a well-performed procedure. Proper orientation within the joint optimizes visualization, access, and instrumentation, despite limitations on maneuverability imposed by the constrained architecture. |
| Avoid iatrogenic damage | Every entry of an instrument into the hip should be performed as carefully as possible. With careful attention to technique, the likelihood of "scope trauma" can be diminished. |
| Avoid excessive labral resection | The damaged tissue must be removed, but avoid resection of healthy labrum, which can lead to poorer results. |
| Avoid advanced disease states | Chondroplasty and débridement in the presence of advanced degenerative disease is unlikely to be successful, despite the appeal of a joint-preserving procedure. |

POSTOPERATIVE CARE

- For most soft tissue procedures, weight bearing is allowed as tolerated, with crutches needed only until the patient’s gait has been normalized, typically 5 or 6 days.
- Home exercises and supervised physical therapy are begun within the first few days.
- Gentle ROM, closed-chain exercises, stabilization, and subsequent functional activities are allowed to progress as dictated by the pathology encountered, the procedure performed, the resources available to the patient, and the patient’s goals for returning to activities.
- For labral repairs, patients are kept on a protective weight-bearing status for 6 weeks, with avoidance of external rotation and maximal hip flexion.
- For microfracture, a strict protective weight-bearing status is maintained for 2 months during early maturation of the fibrocartilaginous healing response.

OUTCOMES

- Successful outcomes from labral débridement range from 68% to 82%.1,12,20
- Diminished results are observed with associated articular damage, which is present in most cases.
• The poorest results are reported in patients with radiographic evidence of arthritis.
• These observations are supported by a recent study reporting 82% continued successful outcomes at 10-year follow-up for patients undergoing labral débridement in absence of arthritis. Among those with associated arthritis, 79% had been converted to total hip arthroplasty.
• Considerable experience has been gained in labral repair, but few outcome data have been published, with preliminary studies reporting success in two thirds of cases.
• These results will improve with a better understanding of patient selection.
• Microfracture of grade IV articular lesions has demonstrated successful outcomes in 86% of properly selected cases.
• Successful results also have been reported with excision of painful unstable fragments caused by macrotrauma.
• Soft tissue impingement due to disrupted fibers of the ligamentum teres tends to be quite painful and responds remarkably well to arthroscopic débridement, with success comparable to loose body removal.
• The results of many of these procedures will continue to improve with better understanding of underlying causative factors such as femoroacetabular impingement.

COMPLICATIONS
• The reported complication rate for hip arthroscopy among large cohorts ranges from 1.3% to 6.4%. Most complications are minor or transient, but a few major problems have been reported.
• Iatrogenic intra-articular damage may be the most common complication. Occasional joint scuffing may not be avoidable, but the concerns can be minimized by use of meticulous technique.
• Traction neuropraxia can be associated with prolonged or excessive traction, but also can occur even when surgery is performed within established guidelines.
• Direct trauma to major neurovascular structures should be avoidable, but, rarely, a partial neuropraxia of the lateral femoral cutaneous nerve can occur in association with the anterior portal.
• Life-threatening intra-abdominal fluid extravasation has been reported, emphasizing the importance of maintaining an awareness of fluid use during surgery.

REFERENCES
DEFINITION

- Femoroacetabular impingement (FAI) is the result of abnormal contact between the proximal femur and the acetabular rim.
- Abnormalities can be identified on either the femoral or acetabular side, but are more commonly seen on both sides.
- This abnormal contact can lead to acetabular chondral lesions and or labral lesions, leading to hip pain and the development of diffuse osteoarthritis of the affected hip if left untreated.\(^1,2,3\)

ANATOMY

- The proximal femur and acetabulum normally articulate without abutment through a physiologic range of motion (ROM).
- The acetabulum normally is anteverted 12 to 16.5 degrees.
- The acetabulum covers the femoral head to a depth that avoids impingement (ie, overcoverage) and instability (ie, dysplasia or undercoverage) with a horizontal, thin, sourcil (ie, the weight-bearing zone).
- The proximal femur has a spherical head-neck contour that allows for impingement-free ROM.
- The normal femoral neck shaft angle is 120 to 135 degrees; the femoral neck typically is anteverted and is 12 to 15 degrees.
- It is important to recognize and respect the location of the retinacular vessels that have been shown to enter the antero- and posterolateral portions of the femoral neck and supply the majority of the femoral head’s blood supply.

PATHOGENESIS

- There are two primary mechanisms of FAI: pincer and cam impingement.\(^1,2,3\)
- Pincer impingement is the result of contact between an abnormal acetabular rim and normal femoral head–neck junction (FIG 1A).
  - Pincer impingement typically is the result of a deep acetabulum (coxa profunda), local anterior overcoverage (acetabular retroversion), or, less commonly, posterior overcoverage.
  - It leads to labral bruising and tearing, and eventually may result in ossification of the labrum and contrecoup posterior acetabular chondral injury.
- Cam impingement is the result of contact between an abnormal femoral head–neck junction and the acetabulum (FIG 1B).
  - The abnormal femoral head neck junction usually is secondary to an aspherical anterolateral head neck junction, but also can be secondary to a slipped capital femoral epiphysis, femoral retroversion, coxa vara, malreduced femoral neck fracture, and, occasionally, posterior femoral head neck abnormalities.
  - Cam impingement results in a shearing stress to the anterosuperior acetabulum, with predictable chondral delamination and labral detachment or tearing in some cases.
Although cam impingement is reported to predominate in young athletic males and pincer impingement in middle-aged women, most patients with FAI have a combination of both cam and pincer impingement.

**NATURAL HISTORY**
- The likelihood of an individual with untreated FAI developing hip osteoarthritis is unknown, because there have been no longitudinal studies prospectively following these patients before the development of symptoms.
- Clinical experience with over 600 surgical dislocations of the hip in patients with FAI has revealed a strong association of this disorder with progressive acetabular chondral degeneration, labral tears, and progressive osteoarthritis.1-3
- It is now well accepted that many patients with FAI will develop progressive chondral and labral injury that can ultimately lead to end-stage hip osteoarthritis.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Patients typically are young to middle aged (2nd through 4th decade) with complaints of groin pain exacerbated by physical activity.
- Prolonged sitting, arising from a chair, putting on shoes and socks, getting in and out of a car, and sitting with their legs crossed often exacerbate the symptoms.
- We have found that patients may have a history of siblings, parents, and grandparents with hip pain or osteoarthritis of the hip, and patients may have milder or similar symptoms in the contralateral hip.
- Patients often have had pain for months to years with the diagnosis of chronic low back pathology, hip flexor strains, and sports hernias, and not infrequently have had other surgeries without relief of their pain.
- Physical examinations should include:
  - Evaluation of hip ROM: global ROM restriction indicates advanced osteoarthritis.
  - Anterior impingement test: groin pain indicates anterolateral rim pathology.
  - Posterior impingement test: groin pain or posterolateral pain indicates posterolateral rim pathology.
  - FABER test: FABER means flexion, abduction, and external rotation of the hip. Increased distance from the lateral knee to the examination table can indicate femoroacetabular impingement.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs including an anteroposterior (AP) pelvis, frog lateral, and ideally a cross-table lateral and false profile view are obtained.
- The AP radiograph should have a coccyx to symphyseal distance of 0 to 2 cm with the coccyx centered over the symphysis to properly evaluate acetabular version.
- The following are measured on the AP radiograph (FIG 2A):
  - A lateral center edge angle of 25 to 40 degrees distinguishes deep acetabulum from dysplasia.
  - The presence of a crossover sign indicates local anterior overcoverage (retroversion).
  - The posterior wall sign indicates posterior undercoverage (retroversion).
  - Cam impingement indicates decreased head-neck offset.
  - A femoral neck shaft angle indicates that coxa vara may contribute to impingement.
- The frog-leg lateral and cross-table lateral views with 15 degrees internal rotation ideally evaluate:
  - Alpha angle: normally less than 50 to 55 degrees (anterolateral prominence/aspherical femoral head neck junction; FIG 2B)
  - Femoral head neck cystic changes and sclerosis
  - Femoral neck version: retroversion may contribute to impingement.
- The false profile is used to evaluate:
  - Anterior center edge angle: anterior over- and undercoverage
- An MRI arthrogram is useful to evaluate for labral and chondral pathology, acetabular retroversion, or a prominence of the femoral head neck junction which is best seen on the axial cuts (FIG 2C).
- Synovial herniation pits at the femoral head neck junction are also indicative of FAI.
- An anesthetic agent should be included with the gadolinium to verify the hip joint as the source of pain, which is indicated by temporary pain relief with provocative maneuvers in the first couple of hours after the injection.
- Occasionally it is helpful to obtain a three-dimensional CT study to appropriately map the area of impingement.

**FIG 2**
- **A.** Lateral center edge angle, posterior wall sign, and crossover sign are depicted. **B.** Alpha (α) angle is elevated in cam impingement. **C.** Prominence of the anterolateral femoral head–neck junction is seen on axial MRI images.
This may be done routinely or in cases of subtle FAI or suspected unusual locations of FAI (e.g., posterior femoral head/neck prominences).

**DIFFERENTIAL DIAGNOSIS**
- Sports hernia or athletic pubalgia
- Lumbar spine pathology
- Gynecologic or urologic pathology
- Intra-abdominal pathology
- Hip flexor pathology or iliopsoas snapping
- Iliotibial band pathology or snapping
- Pelvic stress fracture
- Intra-articular pathology not related to FAI

**NONOPERATIVE MANAGEMENT**
- Nonoperative management of FAI consists of avoiding painful activities such as deep hip flexion, aggressive hip flexion–based weight training, and athletic activities that aggravate symptoms.
- Intra-articular pathology often progresses without symptoms early in the disease, and there is concern that without surgical treatment arthritis eventually will develop.
- Nonoperative management may be best employed in the already degenerative hip with joint space narrowing prior to total hip arthroplasty, and consists of activity modification, core trunk strengthening exercises, and occasional intra-articular corticosteroid or hyaluronic acid injections.

**SURGICAL MANAGEMENT**
- Physical examination and imaging studies consistent with FAI
- Pain despite activity modification
- Pain in patient who is unable or unwilling to modify activity
- Minimal to no degenerative changes
- Arthroscopic versus open procedure for FAI (Table 1)
  - There are no strict indications for open versus arthroscopic management of FAI.

**Table 1**

</table>

The goal of arthroscopy is to reproduce the open approach for managing FAI.

Although controversial, some higher-level athletes may prefer a less invasive arthroscopic approach with a more predictable return to sports.10

**Preoperative Planning**
- Initially, a fluoroscopic evaluation is done, including anteroposterior, frog lateral, and cross-table lateral evaluation of the acetabulum and proximal femur.
- Dynamic fluoroscopic evaluation by abduction of the hip in flexion, external rotation, and extension with internal and external rotation occasionally reveals impingement of the acetabulum on the proximal femur and results in a vacuum effect in the joint as the proximal femur is levered out of the acetabulum.

**Positioning**
- Arthroscopic management of FAI begins with standard hip positioning in either the supine or lateral position.
- We prefer the supine position with the hip in slight flexion, neutral abduction, and internal rotation (FIG 3).

**Approach**
- Most cases can be performed using the standard anterior paratrochanteric and anterior portals, with occasional use of the posterior paratrochanteric or accessory distal portal (FIG 4).
When pincer impingement is present, the labrum is evaluated, including the acetabular labrum, acetabulum, and femoral head articular cartilage; fovea; ligamentum teres; transverse acetabular ligament; and capsular structures (TECH FIG 1A,B).

The peripheral compartment is evaluated, including the femoral head, labrum, zona orbicularis, medial synovial fold, femoral neck, and peripheral capsular attachments (TECH FIG 1C).

The pathology present helps to define the pathologic mechanisms present, with chondral delamination in the anterior superior acetabulum indicating cam impingement (TECH FIG 1D), and labral ecchymosis, tearing, and linear posterior acetabular chondral wear indicating pincer impingement (TECH FIG 1E).

When pincer impingement is present, the labrum is evaluated, and any tearing is carefully débrided, taking care to preserve the peripheral labrum when possible.

If complex tearing of the labrum is present, the labrum is generously débrided; however, the periphery of the labrum often remains intact and is amenable to repair or refixation (TECH FIG 2A).

If the labrum is amenable to repair or refixation, it is carefully detached from the acetabulum using a Beaver blade and shaver, beginning at the periphery and extending to the articular side of the labrum (TECH FIG 2B).

Care must be taken to detach as much of the labrum as possible without cutting too deep on the articular side, which could result in inadvertent delamination of the acetabular articular cartilage.

The labral detachment usually extends from the anterior portal to the 12:00 position. More or less may be detached further, superiorly and posteriorly, depending on the extent of acetabular overcoverage anterolaterally or posteriorly, and should include detachment of all of the torn or ecchymotic labrum.
The labrum then falls into the joint, creating a bucket handle tear, and a 5.5-mm burr is used to trim the acetabular rim to a depth of 5 to 10 mm (TECH FIG 2C,D). An attempt is made to trim all of the acetabulum with abnormal articular cartilage to a residual lateral center edge angle of 25 to 30 degrees, taking more or less according to the preoperative center edge angles. If areas of grade 4 chondromalacia remain after acetabular rim trimming, microfracture is performed on the exposed bone.

Suture anchors (usually two to four anchors) are then placed just under the acetabular subchondral bone, and the sutures are first passed under the labrum and then pulled over or through the labrum, securing the labrum to the rim with standard knot-tying techniques (TECH FIG 2E–G). Care is taken to place the knot on the capsular or medial side of the labrum to avoid damaging the femoral articular cartilage with prominent suture during weight bearing and ROM.

OS ACETABULI/PINCER IMPINGEMENT

Occasionally an os acetabuli is responsible for local anterior overcoverage and typically is attached to the acetabulum just peripheral to the labrum.

The os is exposed and excised using a burr beyond the fibrocartilage attachment of the native acetabulum with or without labral débridement or detachment and refixation (TECH FIG 3).
Exposure of the femoral head–neck junction can be performed using a generous capsulotomy, capsulectomy, or small capsular window.

We prefer a generous capsulotomy beginning anterior to the anterior portal and extending to the posterolateral portal site (TECH FIG 4A).

Traction is then released, and the hip is flexed to varying degrees, allowing for visualization of the peripheral head–neck junction and the cam lesion.

The normal head–neck junction is spherical (TECH FIG 4B), whereas in cam impingement it appears egg-shaped, flat, or with a prominence at the head–neck junction (TECH FIG 4C).

The cam lesion is covered with healthy-appearing articular cartilage with varying mild degrees of eburnation, progressing very early in the process to a more degenerative peripheral head–neck junction with clefts and intraosseous cysts in more advanced cases (TECH FIG 4D).

A 5.5-mm burr is used to reshape the anterolateral prominence, typically removing 5 to 10 mm and occasionally more, depending on the size of the lesion and thickness of the neck (TECH FIG 4E,F).

A recent cadaveric study recommended resecting no more than 30% of the thickness of the femoral neck to avoid pathologic fractures postoperatively.6

A frog lateral and cross-table lateral view with internal rotation are used to verify restoration of a normal alpha angle (TECH FIG 4G,H).

For more superior and posterior lesions, the hip is slowly extended and internally rotated, and the working and
arthroscopic portals can be exchanged from the anterior and anterior paratrochanteric portals to the anterior and posterior paratrochanteric portals for better visualization.

- Care is taken to avoid aggressive resection down the anterolateral and posterolateral regions of the femoral neck to avoid damage to the retinacular vessels which should be visualized and protected throughout the case.
- The typical pattern of cam impingement extends down the neck on the anterolateral femoral head–neck junction and closer to the articular cartilage margin of the femoral head, more superiorly in the region of the retinacular vessels.

Final confirmation of adequate resection is then verified arthroscopically by flexing the hip more than 90 degrees with maximal internal rotation, external rotation, and abduction.

- Capsular closure is then performed with one or two absorbable sutures passed through one side of the capsule with a looped suture passer and grasped through the other side of the capsule (TECH FIG 4I).
- A knot is then tied blindly at the periphery of the capsule using standard arthroscopic knot-tying techniques.
- The hip is then infiltrated with an anesthetic, and the portals are closed in the usual fashion.

**PEARLS AND PITFALLS**

| Indications                  | History, physical examination, and imaging studies should be consistent with femoroacetabular impingement. |
|                             | Intra-articular anesthetic injection should confirm the hip as the source of pain. |

| Exposure                    | Care should be taken to excise the labrum peripherally and detach on the articular surface without undermining the acetabular chondral surface to allow for adequate tissue for refixation. |
|                            | Adequate capsulotomy or capsulectomy should be performed to allow for exposure of the femoral head–neck junction. |
|                            | Flexion, extension, and rotation allow for complete visualization of the femoral head–neck prominence in cam impingement. |

| Pincer                      | Generally 5 mm of acetabulum is trimmed with more removed based on the extent of chondral damage taking care not to create a dysplastic acetabulum based on preoperative center edge angles. |
POSTOPERATIVE CARE

- Pre- and postoperative radiographs confirm adequate osteoplasty and rim trimming (FIG 5).
- Postoperative restrictions are not consistent from one surgeon to the next and are based on the procedures done.

We impose the following restrictions:
- Proximal femoral osteoplasty is treated with protected weight bearing with crutches for 2 weeks and no high-impact or running activities for 2.5 to 3 months.
- Acetabular rim trimming with labral débridement requires no specific restrictions.
- More complex cases of FAI managed arthroscopically can be lengthy procedures, and alternating between traction and flexion or release of traction can help prevent traction-based neuropraxias.
- Meticulous irrigation of all bony debris and postoperative use of nonsteroidal anti-inflammatories can help to minimize the incidence of heterotopic bone formation.

Acetabular labral repair and refixation is treated with toe-touch weight bearing for 2 weeks and avoidance of the extremes of external rotation for 2 weeks.

Microfracture procedures are treated with 6 to 8 weeks of toe-touch weight bearing.

The first 2 months focus on restoration of ROM, gait and pelvic alignment, and gentle core strengthening.

At 2 months, more aggressive core strengthening is instituted, with resumption of full sporting activities at 3 to 6 months based on functional improvement.

Further research is required to develop the optimal rehabilitation programs after the various procedures that have been discussed.

OUTCOMES

Early and midterm results of open procedures for FAI indicate that reduction in pain and functional improvement directly correlate with the degree of osteoarthritic changes found at the time of surgery.1,2,7,9

Some evidence indicates that repair or refixation of the labrum results in improved outcomes when compared to labral débridement or excision in a consecutive series.2,4

It is unclear, however, whether the improvement is the result of labral preservation or of improved technical skills, because the study was performed in a consecutive series of patients.2,4

Little has been published in the literature with respect to outcomes after arthroscopic management of FAI.

In a review of 45 professional and Olympic level athletes with FAI treated arthroscopically, all had symptomatic improvement and returned to play.10

In another series of 320 patients with FAI treated arthroscopically, 90% had elimination of the impingement sign and were reportedly satisfied with their results.12

Larson and Giveans5 prospectively followed 100 patients with FAI treated arthroscopically for up to 3 years, with a statistically significant improvement in Harris hip, SF-12, and visual analogue pain scoring consistent with that seen after open management of FAI.

No well-designed, long-term, or randomized studies have been done to evaluate outcomes of management of FAI to determine whether osteoarthritis has been delayed or prevented in this patient population. Longer-term follow-up and studies of open versus arthroscopic treatment should better define the optimal indications and procedure for patients with FAI.

COMPLICATIONS

Anterolateral femoral cutaneous nerve neuropraxia

Heterotopic bone or myositis ossificans formation

Iatrogenic acetabular and femoral chondral damage

Rarely postoperative femoral neck fracture

Potential for sciatic or pudendal nerve neuropraxia

Potential for avascular necrosis

REFERENCES

DEFINITION
- *Coxa saltans* is a term popularized by Allen and various co-authors.1
  - Initially they described an internal type (iliopsoas tendon) and an external type (iliotibial band).
  - More recently, they proposed an intra-articular type, which is simply a catch-all for numerous intra-articular lesions.
- Snapping hip syndrome most clearly represents an extra-articular dynamic tendinous phenomenon of either the iliopsoas tendon or iliotibial band.

ANATOMY
- The iliopsoas complex, a powerful hip flexor, is formed from the psoas major and iliacus muscles (FIG 1A).
  - The psoas major originates from the lumbar transverse processes and the sides of the vertebral bodies and intervertebral discs from T12 to L5; the iliacus originates from the superior two thirds of the iliac fossa, the sacral ala, and the anterior sacroiliac ligaments.
  - The tendon forms first from the psoas proximal to the inguinal ligament and then rotates such that its anterior surface comes to lie medial and its posterior surface lateral.
  - The tendon then spreads out to insert over the lesser trochanter.
  - It is joined by an accessory tendon from the iliacus, and the tendons then fuse together before forming the enthesis of the iliopsoas. Some muscle fibers of the iliacus remain separate, attaching directly to bone.
  - In the sagittal plane, as the iliopsoas exits the pelvis, it is redirected 40 to 45 degrees over the pectineal eminence toward its insertion site.
- Iliotibial band (FIG 1B): The fascia lata covers the entire hip region, encasing its three superficial muscles, ie, the tensor fascia lata, sartorius, and gluteus maximus.
  - A confluence of the tensor fascia lata and gluteus maximus forms the iliotibial band.
  - The gluteus maximus also partly inserts into the proximal femur at the gluteal tuberosity.
  - This fibromuscular sheath was described by Henry7 as the “pelvic deltoid,” reflecting on the fashion in which it covers the hip, much as the deltoid muscle covers the shoulder.

PATHOGENESIS
- The snapping occurs as the iliopsoas tendon subluxes from lateral to medial while the hip is brought from a flexed abducted, externally rotated position into extension with internal rotation (FIG 2A,B).
- It is variously proposed that the anterior aspect of the femoral head and capsule, or pectineal eminence, is...
responsible for transiently impeding the tendon and creating the snapping.

- Incidental asymptomatic snapping of the iliopsoas tendon is estimated to be present in at least 10% of a normal, active population.
- Painful snapping may be precipitated by macrotrauma or repetitive microtrauma in patients with a predilection for certain activities such as ballet.
- The exact structural alteration that occurs when symptomatic snapping develops has not been defined.
- The snapping occurs as the iliotibial band flips back and forth across the greater trochanter, and often is attributed to a thickening of the posterior part of the iliotibial tract or anterior border of the gluteus medius (FIG 2C).
- The thickened portion lies posterior to the trochanter in extension and flips forward as the hip begins to flex.
- Coxa vara and reduced bi-iliac width have been proposed as predisposing anatomic factors.
- Tightness of the iliotibial band also may be an exacerbating factor.
- Like snapping of the iliopsoas tendon, snapping of the iliotibial band may be an incidental finding without precipitating cause or symptoms.
- Painful snapping may occur following trauma, but is more commonly associated with repetitive activities, classically being described in the downhill leg of runners training on a sloped roadside surface.
- It also has been reported as an iatrogenic process following surgical procedures that leave the greater trochanter more prominent, or reconstructive procedures around the knee that alter the iliotibial band.

**NATURAL HISTORY**

- For most people, the snapping hip remains asymptomatic, never requiring treatment.
- In patients in whom the snapping hip is symptomatic, the course is variable, but there are no apparent long-term consequences of a chronic snapping hip.
- Spontaneous resolution may occur but is uncommon.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

**Iliopsoas Tendon**

- The history of onset of symptoms is variable and may be insidious, owing to specific repetitive maneuvers or an acute injury.
- The patient typically describes a clicking sensation emanating from deep within the anterior groin, which often is audible enough to be characterized as a “clunk.”
- Although the symptoms typically are referred to the anterior groin, some patients may describe flank or sacroiliac discomfort, reflecting irritation around the origin of the psoas and iliacus muscles.
- The characteristic examination maneuver is performed with the patient lying supine, bringing the hip from a flexed, abducted, externally rotated position down into extension with internal rotation, creating the snap.
- Sometimes this is a dynamic process that the patient can demonstrate actively better than the examiner can produce passively. Although often prominent, it may be subtle, and may occur more as a sensation experienced by the patient rather than one that the examiner can observe objectively.
Applying pressure over the anterior joint can block the tendon from snapping and assist in confirming the diagnosis. Variously, patients may be able to demonstrate this best lying, sitting, or standing, or with walking. However, regardless of the position, the snapping uniformly occurs as the hip goes from a flexed toward an extended position.

Iliotibial Band
- As with the iliopsoas tendon, patients may describe the onset of symptoms as being insidious, due to specific repetitive activities, or in response to acute trauma.
- Whereas snapping of the iliopsoas tendon often can be heard from across the room, snapping of the iliotibial band can be seen from across the room.
- Patients describe a sense that the hip is subluxing or dislocating. This is termed “pseudosubluxation,” because the visual appearance may suggest that the hip is subluxing but radiographs uniformly demonstrate that the hip remains concentrically reduced.
- The patient always relates a snapping or subluxation-type sensation. The symptoms are located laterally, and patients typically can illustrate this while standing.
- As with the iliopsoas, this often is a dynamic process, better demonstrated by the patient than produced by passive examination. It may be detected with the patient lying on the side and then passively flexing and extending the hip.
- The snap can be palpated over the greater trochanter, and its origin is confirmed by applying pressure, which can block the snap from occurring.
- The Ober test evaluates for tightness of the iliotibial band, which may accompany symptomatic snapping.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The diagnosis of a snapping iliopsoas tendon is based primarily on the history and physical examination.
- Iliopsoas bursography and ultrasonography may be helpful to rule in, but not rule out, the diagnosis (FIG 3).
- These imaging modalities are technically limited because of a significant rate of false-negative interpretation.

Similarly, snapping of the iliotibial band is based on the clinical assessment, and investigative studies offer little aid in substantiating or discounting the diagnosis. Nonetheless, plain radiographs remain an essential tool in the assessment of any hip problem, and other investigative studies such as MRI and magnetic resonance arthrography may be important to evaluate for associated conditions such as intra-articular pathology.

DIFFERENTIAL DIAGNOSIS
- Snapping iliopsoas tendon
- Hip instability
- Snapping iliopsoas tendon
- Intra-articular pathology
- Pelvic instability (eg, sacroiliac joint or symphysis pubis)
- Osteochondroma

NONOPERATIVE MANAGEMENT
- Treatment often involves little more than establishing the diagnosis and assuring the patient that the snapping is not harmful or indicative of future problems.
- Oral anti-inflammatory medications may be helpful in addition to a flexibility and stabilization exercise program.
- For recalcitrant cases:
  - A period of activity modification to diminish symptoms may be necessary.
  - Judicious use of corticosteroid injections may be appropriate, with the goal of providing transient improvement to supplement the effect of other therapeutic modalities.

SURGICAL MANAGEMENT
- Various open procedures have been described for releasing the tendinous portion of the iliopsoas, with generally favorable results. However, superior results have been reported with endoscopic methods. These superior results are due only partly to the less invasive nature of the technique.
- Most cases with a painful snapping iliopsoas tendon also were found to have associated intra-articular pathology, which also was addressed.

FIG 3 • Iliopsoas bursography silhouettes the iliopsoas tendon (arrows) with contrast. A. In flexion, the iliopsoas tendon lies lateral to the femoral head. B. In extension, the iliopsoas tendon moves medial. (Courtesy of J. W. Thomas Byrd, MD.)
Failure to inspect the interior of the hip joint and address associated pathology may be a significant contributing factor to less optimal results with traditional open techniques.

**Iliotibial Band**
- Various techniques have been described for correcting snapping of the iliotibial band.
- One complex procedure is a Z-plasty lengthening, the results of which have ranged from poor to good.2,10,11
- Several techniques have employed a simpler approach, creating a relaxing incision in the portion of the iliotibial band over the greater trochanter, and these have shown to be effective at eliminating the snapping in most cases.3,15
- Violation of the tendon structure is minimized, which diminishes the morbidity of the procedure and facilitates the postoperative recovery.
- Endoscopic methods have been developed that may accomplish this same goal.8

**Preoperative Planning**
- Clinical assessment of the snapping iliopsoas tendon and iliotibial band is relatively straightforward.
- However, careful assessment is necessary to ensure that the snapping is clearly the source of the patient’s symptoms and also to evaluate other associated conditions, especially concomitant intra-articular pathology.
- Perhaps most important is a careful assessment of the patient’s motivation, understanding, and goals of recovery.
- It is important to bear in mind that coxa saltans often is encountered in asymptomatic individuals.
- Surgery is considered only if the patient has exhausted efforts at conservative treatment and demonstrates sufficient motivation for the postoperative recovery.

**Positioning**
- **Iliopsoas tendon**
  - Endoscopic release of the iliopsoas tendon is performed in conjunction with routine arthroscopy of the joint.
  - Arthroscopy can be performed with the patient in either the supine or lateral position.
  - The supine position may provide better access to these structures, and is the method described.
- **Iliotibial band**
  - Open procedures employ the lateral decubitus position, and this also has been the preferred orientation for endoscopic methods.

**Approach**
- **Iliopsoas tendon**
  - Most endoscopic reports have described releasing the tendon from its insertion on the lesser trochanter within the iliopsoas bursa.4,5
  - This is the endoscopic counterpart to the open method described by Taylor and Clarke.12 For the occasional case of a snapping iliopsoas tendon associated with a total hip arthroplasty, it clearly is the preferred approach.
  - Another endoscopic technique, in which the iliopsoas tendon is approached from the peripheral compartment, seems to provide a comparable effect of releasing the tendon.14
  - The method is analogous to the open method described by Allen et al.1 Theoretically, it may have an advantage of reduced morbidity.
- **Iliotibial band**
  - The various open approaches use a common, lateral, longitudinal incision over the greater trochanter.
  - Endoscopic methods employ laterally based portals, approaching the tendon from its superficial subcutaneous surface.

**ENDOSCOPIC ILIOPSOAS RELEASE**

**Lesser Trochanter (Iliopsoas Bursa)**
- After completing routine hip arthroscopy, including intra-articular and peripheral compartments, the leg is repositioned in 20 degrees of flexion and full external rotation.
- Slight flexion partially relaxes the tendon but maintains some tension.
- External rotation brings the lesser trochanter more anterior for access from the laterally based portals (TECH FIG 1A).
- A portal is established distal to the standard anterolateral hip portal at the level of the lesser trochanter, using fluoroscopic guidance (TECH FIG 1B).
  - This exposes the tendon within the iliopsoas bursa, which is the largest bursa in the body.
- Another portal is then placed distally, converging toward the lesser trochanter (TECH FIG 1C).
- The arthroscope and instruments are switched between these two portals for thorough visualization and instrumentation of the iliopsoas tendon (TECH FIG 1D).
- Adhesions within the bursa can be cleared, providing excellent visualization of the iliopsoas tendon.

**Peripheral Compartment**
- After completing arthroscopy of the intra-articular compartment with a standard supine technique, the traction is released, the hip is flexed 45 degrees, and standard portals are established in the peripheral compartment (TECH FIG 2).
- The iliopsoas tendon can be exposed in line with the medial synovial fold, proximal to the zona orbicularis.
  - Occasionally, a communication is present at this location between the joint and the iliopsoas bursa.
  - If no communication is present, a capsular window can be created with a shaver.
- The capsule in this location is thin, and often the tendon is visible or palpable through the thin capsule.
**TECH FIG 1** • Release of right iliopsoas tendon from lesser trochanter. **A.** The hip is flexed approximately 20 degrees and externally rotated. **B.** Initial portal established at level of lesser trochanter. **C.** Ancillary portal is established distally under direct arthroscopic visualization. **D.** The arthroscope has been switched to the more distal portal with a flexible radiofrequency (RF) device introduced proximally. **E.** Arthroscopic illustration shows release of the tendinous portion of the iliopsoas. (Courtesy of J. W. Thomas Byrd, MD.)

**TECH FIG 2** • Arthroscopic view from the peripheral compartment of a right hip. **A.** A window (arrows) has been created through the thin medial capsule, exposing the iliopsoas tendon (*) anterior to the femoral head (FH). **B.** The tendinous portion is released with a basket. **C.** The final fibers are débrided with a power shaver. **D.** Through the capsular window (arrows) the tendon has been completely released, preserving the muscular fibers (*). The relation between the capsular window and the acetabular labrum (AL) and femoral head (FH) is identified. (Courtesy of J. W. Thomas Byrd, MD.)
TENDOPLASTY OF THE ILIOTIBIAL BAND

Open Technique

- A straight, lateral longitudinal incision is centered over the greater trochanter (TECH FIG 3).
- The length is dictated by the amount of exposure needed to precisely accomplish the tenodopasty.
- A smaller incision is more cosmetic and can be accomplished with dissection of the subcutaneous tissues and selective retraction but should not compromise visualization for the procedure.
- Several authors have described variations of a similar method for relaxing the tendon. These are based on an 8- to 10-cm longitudinal incision just posterior to the mid part of the greater trochanter in the thickest portion of the iliotibial band.
- Relaxation of the tendon is completed with paired or staggered 1- to 1.5-cm transverse incisions.
- The field is relatively bloodless, but meticulous hemostasis should be maintained and the subcutaneous tissues closed in layers to avoid formation of a hematoma.

Endoscopic Technique

- Two portals are used: one 3 cm proximal to the tip of the greater trochanter and one 3 cm distal.
- The arthroscope is placed from the distal portal site down to the subcutaneous surface of the iliotibial band.
- Then, with arthroscopic visualization, the proximal portal is established for dissection to release the subcutaneous tissue from the superficial surface of the tendon (TECH FIG 4).
- A 4- to 5-cm longitudinal incision within the tendon is created using a shaver and a radiofrequency (RF) probe.
- An anteriorly based transverse incision is then made and the flaps resected, creating a long, obtuse triangle.
- This provides better visualization to determine the relation of the iliotibial band and the underlying greater trochanter.
- Portions of the trochanteric bursa can be resected as necessary for treatment and clearing the field of view.
- Lastly, a posterior transverse incision is made and the flaps excised, creating a diamond-shaped pattern of resection.
- Hemostasis should be meticulously maintained and a compressive dressing applied to minimize the formation of a hematoma.

If the glistening tendon is not immediately visible, it should come into view after the capsular window is extended laterally.

At the level of the joint, the tendon fibers of the iliopsoas lie on the posterior surface of its muscular portion.

The muscular portion separates the tendon from the femoral nerve, which is the most lateral of the femoral neurovascular structures.

The tendon can be transected with a combination of hand biter instruments, power shaver, and thermal device.

TECH FIG 3 • Our preferred approach includes an 8- to 10-cm longitudinal incision, posterior to the midpoint of the greater trochanter, with two pairs of 1- to 1.5-cm transverse incisions. This relaxes the iliotibial band, eliminating the snapping, without creating any suture repair lines that would necessitate prolonged convalescence. A. Incision pattern. B. Relaxing response to incision. C. Appearance at surgery. (Courtesy of J. W. Thomas Byrd, MD.)
TECH FIG 4 • Endoscopic method of iliotibial band tendoplasty, shown in the right hip. A. After creating the longitudinal incision, the anterior limb is created by a perpendicular incision. B. Resecting the edges creates a triangle that aids in visualization of the underlying structures. C. The posterior limb is then created, and resection completes the diamond pattern of the tendoplasty. (Adapted from Ilizaliturri VM Jr, Martinez-Escalante FA, Chaidez PA, et al. Endoscopic iliotibial band release for external snapping hip syndrome. Arthroscopy 2006;22:505–510.)

PEARLS AND PITFALLS

Visualization
■ With any endoscopic technique, good visualization is essential. Poor visualization will result in a poorly performed procedure. Visualization is facilitated by use of a high-flow fluid management system and control of hemostasis by keeping the systolic blood pressure below 100 mm Hg, adding diluted epinephrine to the fluid, and judicious use of cautery.

Violation of iliopsoas tendon
■ Surgical violation of the iliopsoas tendon carries the risk of heterotopic ossification, in either an open or arthroscopic procedure. It is prudent to use pharmacologic prophylaxis for this condition.

Failure to fully release tendon
■ The iliopsoas tendon forms from the psoas and iliacus muscles. The tendon sometimes may remain bifid all the way to its insertion on the lesser trochanter. Whether addressing the tendon from the peripheral compartment (FIG 4A-G) or from its insertion within the iliopsoas bursa (FIG 4H,I), if the tendon looks inordinately small, search for a separate portion of the tendon. Failure to fully release the tendon fibers may result in incomplete resolution of the snapping.

Inadequate tendoplasty
■ Inadequate tendoplasty of the iliotibial band can result in incomplete resolution of symptoms; but excessive release can compromise the functional integrity of the abductor mechanism, rendering it virtually unsalvageable.

Proper diagnosis
■ With proper diagnosis, the surgical results for snapping of the iliopsoas tendon and the iliotibial band are highly predictable and finite in terms of resolution of the snapping.
■ However, the subjective response to surgery is highly dependent on the patient’s expectations and motivations, which are equally essential in the evaluation process.
POSTOPERATIVE CARE

- After these procedures, the patient is capable of full weight bearing, but crutches are used for about 2 weeks until the gait pattern is normalized.
- Gentle range-of-motion, closed-chain, and stabilization exercises are introduced as symptoms allow.
- For iliopsoas release, aggressive hip flexion strengthening is avoided for the first 6 weeks; for the iliotibial band, aggressive stretching generally is not necessary.
- The patient should not anticipate returning to vigorous activities for at least 3 months.

OUTCOMES

- For endoscopic release of the iliopsoas tendon, several studies have reported highly predictable results in terms of eliminating the snapping and patient satisfaction.\textsuperscript{3,9}
- However, we have observed two cases of heterotopic ossification that occurred following release of the iliopsoas tendon from the lesser trochanter.

These observations are consistent with reports in the literature on open techniques of the iliopsoas tendon that have noted a propensity for heterotopic bone formation.\textsuperscript{13}

- For snapping of the iliotibial band, tendon-relaxing procedures that maintain the structural integrity of the abductor mechanism, whether performed open or endoscopically, have predictably corrected the snapping with minimal morbidity.\textsuperscript{3,8,15}

FIG 4 • A–G. The iliopsoas tendon of the right hip is exposed from the peripheral compartment. A. The initial tendon viewed through a capsular window is fully identified, but is abnormally small. B. This tendon is released with a basket. C. A stump remains. D. This is resected with a shaver. E. Further dissection exposes a more substantial portion of the iliopsoas tendon. F. This is released as well. G. Complete release of the bifid tendon is documented. H, I. Viewing the iliopsoas tendon of a right hip at its insertion on the lesser trochanter within the iliopsoas bursa. H. A bifid iliopsoas tendon is identified with medial (*) and lateral (**) bands separated by a vessel (two white asterisks) coursing perpendicular. I. The lateral band (black asterisks) has been released with a flexible RF device, revealing the medial band (white asterisk) which subsequently is released. (Courtesy of J. W. Thomas Byrd, MD.)

COMPlications

- No reports have been published of complications with endoscopic release of the iliopsoas tendon.
- We have observed two cases of heterotopic ossification, for which the use of pharmacologic prophylaxis is recommended.\textsuperscript{13}
- Potential complication due to damage to surrounding structures (eg, femoral neurovascular bundle)
- No complications have been reported in conjunction with the less extensive tendon-relaxing procedures for a snapping iliotibial band. Careful attention to the precision of the release
can help avoid inadequate or excessive tendoplasty. Inadequate release could result in residual symptoms, whereas excessive release could result in a virtually unsalvageable compromise of the abductor mechanism.

REFERENCES

DEFINITION
- **Athletic pubalgia** refers to a range of groin injuries in athletes. The terms *athletic pubalgia* and *sports hernia* sometimes are used interchangeably.
- Diagnosis of the cause of groin pain is difficult, because the anatomy is complex and two or more injuries may coexist.
  - Intra-abdominal pathology, genitourinary abnormalities, referred lumbosacral pain, and hip joint disorders must first be excluded.
  - Adductor strains are the most common cause of groin pain in athletes.
  - The adductors usually are strained in an eccentric contraction, often one that occurs at the myotendinous junction, but the strain also can occur in the tendon itself or its bony insertion.
  - Other muscles in and around the groin region also can be strained, including the rectus femoris, the sartorius, and the abdominal muscles, as can the conjoint tendon.
- **Sports hernia** is a condition of chronic groin pain that is caused by a tear in the inguinal floor without a clinically obvious hernia.8,12
  - It results in an occult injury that usually is not identified by most examiners. However, with increasing experience, the examiner can feel an abnormal inguinal floor and appreciate abnormal tenderness inside the external ring.
- In contrast, indirect and direct hernias involve easily palpable defects in the inguinal canal or through the anterior abdominal musculature, respectively.
- Duration of symptoms typically is months, and pain is resistant to conservative measures.
- **Osteitis pubis** is characterized by symphysis pain and joint disruption and occurs commonly in distance runners and soccer players.
  - It may be difficult to distinguish from adductor strains, and the two conditions may coincide.
  - Stress fractures are rare injuries that result from repetitive cyclic loading of the bone.
  - The pubic rami are the most common location for stress fractures in the pelvis. These fractures are most common in long distance runners.

ANATOMY
- The anatomy in and around the groin is complex (FIG 1), and a thorough understanding of it is crucial in diagnosing the various groin injuries.
  - Thorough knowledge of the origins and insertions is very helpful during examination and palpation of the area.
  - The posterior inguinal wall consists primarily of the transversalis fascia, along with the conjoint tendon, made up of the internal abdominal oblique and transversus abdominis aponeuroses.8

![FIG 1 • Anatomy of the abdominal (A) and groin (B) musculature.](image)
The conjoint tendon inserts onto the pubic tubercle and along the iliopubic track.
The pubic symphysis is a rigid, nonsynovial, amphiarthrodial joint consisting of layers of hyaline cartilage encasing a fibrocartilaginous disc.

**PATHOGENESIS**
- Adductor strains are most commonly seen in soccer or ice hockey players.
  - Most happen acutely, and the patient recalls a sudden intense pain in the groin.
  - Eventually the medial thigh swells and ecchymosis is noted over the next 2 to 3 days.
  - The pain improves when the muscle warms up.
- Sports hernia is seen in competitive athletes and occasional work injuries and may involve a particular traumatic episode, but most times is insidious and worsens over time with overuse.
  - Patients describe a deep, disabling groin pain.
  - Kicking and endurance running tend to increase the symptoms.
  - Coughing or Valsalva maneuver increases intra-abdominal pressure and can increase tenderness, as can a resisted sit-up.
- The most likely mechanism for osteitis pubis is that of increased forces placed on the symphysis pubis from the pull of the pelvic musculature or repetitive stress from increased shearing forces.
  - Some cases of osteitis pubis probably are secondary to or coexist with a sports hernia.
- Stress fractures of the pubic rami present as an insidious onset of deep pelvic and groin pain that is worsened after high-impact exercises.
  - The pain is worse immediately during and after the activity and improves with rest.
  - These injuries usually occur in conjunction with an acute increase in the intensity of training.

**NATURAL HISTORY**
- Acute adductor strains, if not properly rehabilitated, may progress to chronic strains or tendinopathy.
- Most patients with sports hernia have had a prolonged course of conservative treatment with continued pain and do not get better. A hallmark of sports hernias is that patients have less pain when they are inactive and more pain when active.
- Osteitis pubis is self-limited but may take, on average, about 9 months to heal.
  - If the stress fracture is not addressed, pain will continue to increase and can be debilitating.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Patient history is the most important aspect of the evaluation of athletic pubalgia.
  - The patient must be asked for duration of symptoms, any inciting events, relieving and exacerbating factors, and timing of pain.
  - To directly assess for hernia:
    - In men: insert the finger into inguinal ring at level of external opening. Invaginate the loose scrotal skin and gently insert the finger into the external ring (FIG 2). Gently feel the inguinal floor and ask the patient to perform the Valsalva maneuver. One can occasionally feel the tear tighten on one's fingertip. Apply gentle pressure medially and laterally looking for abnormal asymmetric tenderness.
    - In women: palpate the superior aspect of the labia majora and upward to lateral to the pubic tubercle.
    - The groin is examined using these methods:
      - Straight leg raise: In patients with radicular low back pain, this will reproduce the pain they are having.
      - Palpation of insertion of conjoint tendon: tenderness may increase, and a bulge may be felt by having the patient perform a Valsalva maneuver.
      - Palpation of the adductor tendon: helps to diagnose an adductor strain or tear
      - Groin adduction resistance: helps to diagnose an adductor strain or tear
      - Palpation of the pubic symphysis: characteristic of osteitis pubis
      - Hip range of motion (ROM) may isolate a source of pain arising from the hip.
      - Thomas test: tightness in extension is a sign of a tight iliopsoas muscle.
      - Hip extension against resistance tests the strength of the hip extensors.
      - Hip flexion against resistance: tests the strength of the iliopsoas and may detect a strain or tear of this muscle.
      - Ober’s test: patient inability to lower the upper leg completely to the examination table is pathognomonic of a tight iliotibial band.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs can be helpful in excluding fractures or avulsions.
- Stress fractures usually are not evident on radiographs.
Bone scanning or MRI is most sensitive, especially in the early stages.

MRI can be used to confirm muscle strain or tears, and partial or complete tendon tears (FIG 3A).

MRI has been used to detect sports hernias, although it is not always successful.\(^3\)

Dynamic ultrasound has been found, in certain cases, to detect posterior wall defects but is highly operator dependent.\(^16\)

Radiographs, CT scans, and bone scans can rule out other diagnoses; none are reliable in detecting sports hernias.

Herniography, which involves an intraperitoneal injection of contrast dye followed by fluoroscopy or radiography, has been shown to identify sports hernias but has limited sensitivity and a substantial risk of perforation in up to 5% of patients.\(^2\)

Osteitis pubis has characteristic radiologic findings, including bone resorption, widening of the pubic symphysis, and irregular contour of articular surfaces or periarticular sclerosis (FIG 3B).

A bone scan may show increased uptake in the area of the pubic symphysis in osteitis pubis; however, not all patients who have symptoms show an abnormality.\(^13\)

MRI has become increasingly useful in the diagnosis of osteitis pubis. Findings can include bone marrow edema or symphyseal disc extrusion.\(^15\)

**DIFFERENTIAL DIAGNOSIS**

- Groin disruption or strain
- Osteitis pubis
- Pelvic stress fractures
- Indirect and direct hernia
- Avascular necrosis of the hip
- Labral tear of the hip
- Hip osteoarthritis
- Abdominal muscle tear
- Lumbar radiculopathy
- Nerve entrapment
- Tumors
- Genitourinary problems
- Inflammatory bowel disease
- Endometriosis
- Pelvic inflammatory disease

**NONOPERATIVE MANAGEMENT**

- Acute treatment of adductor strain includes rest, ice, compression, and elevation.
- The next goal is restoration of ROM and prevention of atrophy. Once the patient can tolerate this, the focus should be to regain strength, flexibility, and endurance.\(^9\)
- Nonoperative management of sports hernia includes physical therapy,\(^10\) anti-inflammatory drugs, and corticosteroid injections at the site of pain.\(^1\)
- Osteitis pubis is a self-limiting condition; therapy should focus on hip ROM, as well as adductor stretching and strengthening.
- Corticosteroid injection in osteitis pubis is controversial but may be helpful in select populations of athletic patients.\(^11,15\)
- Treatment in pelvic stress fractures is straightforward and involves 4 to 6 weeks of rest from the activities aggravating the area.

**SURGICAL MANAGEMENT**

- Many approaches have been tried in the surgical management of sports hernias.
- Tissue repairs require longer rehabilitation and pose a greater risk for recurrence, primarily because of collagenases which are currently being described.
- Laparoscopic repairs fail too often because they do not deal with the anterior mechanisms of groin pain.
- Purely anterior repairs fail occasionally because they do not provide adequate posterior support.
- Mesh repairs are standard.
  - Some mesh repairs fail because the mesh chosen is too heavy and tightly woven.
  - Other mesh repairs fail because of surgical technique (eg, metal tackers, permanent sutures in the periosteum, tight sutures involving nerves and causing necrotic tissue).
- The most logical and successful repair is the use of two-layered lightweight mesh, which provides both posterior and anterior support and allows normalization of the torn anatomy.
Preoperative Planning

- Preoperative planning involves extreme care to ascertain that the patient really does have the injury for which surgery is being planned. This requires a complete history and physical examination performed by an examiner who understands the pathophysiology of this injury.
- Imaging is valuable to rule out alternative pathology.
- Preemptive analgesia is important to reduce postoperative pain and to make the anesthetic experience smoother. Also, local anesthesia is bactericidal, reducing the risk of infection.
- We suggest 1/2% lidocaine with epinephrine and sodium bicarbonate.

Positioning
- The patient is positioned supine and draped.

ULTRAPRO HERNIA SYSTEM (JOHNSON & JOHNSON GATEWAY)

Incision, Dissection, and Site Evaluation

- The incision is made along the path of the inguinal ligament, perhaps 1 cm medial and superior to the ligament. A length of 5 to 6 cm is adequate.
- Dissection is performed down to the external oblique tying veins. Too much cautery increases the risk of a subcutaneous infection.
- The external oblique is incised to the external ring, and the fascia is mobilized both medially and laterally.
- The spermatic cord is carefully evaluated and mobilized, looking for an indirect sac.
- The inguinal floor is carefully evaluated, looking for a torn transversalis fascia or a torn transversus abdominis.
- Occasionally, the yellow preperitoneal fat can be seen outlining a tear.
- The inguinal floor is palpated. The disruption often can be felt.

TECH FIG 1 • A, B. The anterior pocket is developed under the external oblique to optimize placement of the onlay patch and dissected out laterally to ensure the onlay patch will lie flat. C. After the posterior wall has been opened, visual confirmation is made of location in the preperitoneal space by identifying the yellow preperitoneal fat and by visualizing Cooper’s ligament. D. Then, using the forefinger, sweep circumferentially medial, then lateral to actualize the preperitoneal space. (continued)
TECH FIG 1 • (continued) E,F. With the onlay patch grasped down to the connector with sponge forceps, insert the device completely into the defect and deploy the underlay with forceps or finger. (Courtesy of Ethicon Surgery, a Johnson & Johnson company.)

### Positioning the Patches
- The preperitoneal space is opened and prepared. Dissection is extended out laterally so the onlay patch will lie flat (TECH FIG 1A,B).
  - It should be possible to clearly feel under the rectus, the pubis, Cooper’s ligament, and up along the iliofemoral vessels (TECH FIG 1C,D).
- The posterior (round) patch of the UHSL is positioned in the space that has been prepared (TECH FIG 1E,F).
- The transversalis and transversus abdominis are closed around the connector with an absorbable suture tied loosely (an air knot). The technique is evolving, and in the near future, the mesh probably will be attached with tissue glue.

### Affixing the Patches
- The onlay patch is attached to the fascia overlying the pubic tubercle, to the internal oblique fascia medially and to the iliopubic track laterally.
  - A lateral slit is made in the mesh for the spermatic cord, attaching the mesh to the shelving edge of the inguinal ligament. Excess mesh is trimmed away.
  - The mesh should never be tight, and fewer sutures are better than many, as long as the mesh is anatomically placed (TECH FIG 2A–C).
- Marcaine is injected thoroughly, and the external oblique, Scarpa’s fascia, and skin are closed with an absorbable suture (TECH FIG 2D,E).

TECH FIG 2 • A,B. Sutures are used to fixate the onlay patch over the pubic tubercle (essential) and to the mid-portion of the transverse aponeurotic arch (optional). A slit is created in the onlay patch to accommodate the spermatic cord, and the mesh is sutured to close the slit. C. The spermatic cord comes through the onlay patch. (continued)
SPORTS MEDICINE • Section III HIP

PEARLS AND PITFALLS

Operate only if the patient has a good mechanism of injury, a good history, and clear indications on physical examination.

- If the patient’s pain does not improve with rest, he or she probably does not have a sports hernia.

Tight sutures, tacks, or tight mesh may cause chronic postoperative pain.

- For the best results, both the anterior and posterior mechanisms of pain must be addressed.

The principle of this surgery (and all abdominal wall hernia surgery) is to normalize the tissue and reinforce the normalized tissue with lightweight, flexible mesh.

POSTOPERATIVE CARE

- Standard post-inguinal hernia surgery care is advised.
- It is important to emphasize a rapid return to normal nonphysical activity (starting the day after surgery) and a progressive incremental return to sports and working out in preparation for sports. This is best accomplished with the help of a trainer.
- The goal of rehabilitation is to establish a full and normal ROM and flexibility followed by incremental increases in resistance for strength training.
- Contact athletes should be able to return to competition in 3 to 4 weeks.
- Runners should be running in 2 weeks and golfers golfing in 1 week.

OUTCOMES

- With appropriate indications and surgical technique, success rates in sports hernia repair have been as high as 97% to 100% in high-performance athletes, with success measured as a return to previous levels of performance and freedom from pain.

COMPlications

- Recurrence
- Thigh pain in the early postoperative period
- Infection
- Hematoma
- Continued pain

REFERENCES

DEFINITION
- Groin injuries are common among athletes, accounting for 2% to 5% of all athletic injuries.  
- A broad spectrum of pathology can cause groin pain in the athlete, and the differential diagnosis is critical.
- Adductor longus–related pain is the most common entity, particularly in athletes participating in kicking sports, such as soccer, and in sports requiring rapid directional changes such as ice hockey and American football.
- Most acute adductor-related groin pain represents strain at the muscle–tendon junction. Although rare, complete avulsions of the adductor longus origin from the pubis can occur.
- Chronic adductor pain typically occurs as an isolated enthesopathy or in concert with athletic pubalgia or pre-hernia complex.

ANATOMY
- The adductor longus is a large, fan-shaped muscle that originates from the anteromedial aspect of the superior pubic ramus just inferior to the pubic tubercle and inserts on the linea aspera of the femur.
- Innervated by the anterior division of the obturator nerve, the origin of the adductor longus consists of direct attachment of both muscle fibers and tendon to the pubis. The proximal tendon has a narrow cross-sectional area.
- The proximal tendon is readily identified on the anterior surface of the muscle with an oblique muscle–tendon junction. The proximal posterior surface usually is entirely muscular in origin.
- A common anomaly is muscle fibers forming the lateral 5 to 11 mm of the anterior origin.
- In maturity, the fibrocartilage of the symphysis pubis develops a small, central fluid-filled cavity or cleft. This cleft manifests as a central focus of high signal intensity at T2-weighted and fat-suppressed short T1 inversion recovery (STIR) imaging.

PATHOGENESIS
- The pathogenesis of chronic adductor strains and frequently associated sports hernias or athletic pubalgia is poorly understood.
- The problem usually is seen in athletes using powerful and ballistic muscle action involving a rapid change from a trunk rotated posteriorly to the plant foot with simultaneous hip extension and abduction followed by a sudden anterior trunk rotation with hip flexion and adduction.
- Examples are an in-step kick in soccer or a fast gait in hockey when the trailing leg is pulled forward, where these actions create strong muscle activity around the lower abdominal muscles and hip adductors and flexors.
- Many of these conditions are chronic or acute on chronic.
- The possibility of a subtle degree of pelvic instability has been considered, but it is difficult to prove.
- Hip adductor involvement is more likely an abnormality at the insertion than a chronic tendinitis or tendinosis.

NATURAL HISTORY
- Acute adductor strains at the musculotendinous junction, like other muscle strain injuries, vary considerably in time to recovery based on the severity of the injury. These are almost always managed without surgery.
- Prior adductor strain has been shown to be a significant risk factor for injury.
- An adductor-to-abductor muscle strength ratio of less than 80% is predictive for a future adductor strain as well. Preventive hip strengthening regimens can lower the incidence of adductor strains.
- In the rare instance of a complete adductor longus avulsion, nonoperative management is preferred.
- Chronic adductor pain presenting as an enthesopathy may occur simultaneously with athletic pubalgia or may follow an acute strain. Enthesopathy can lead to resistant, chronic groin pain, warranting operative intervention.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The diagnosis of an acute adductor strain is relatively straightforward, because the athlete typically presents with a sudden injury to the groin incurred during athletic competition.
- There is tenderness to palpation at the muscle tendon junction. This pain is exacerbated with resisted adduction and passive abduction. Imaging rarely is required for acute strains, but is more commonly obtained for professional athletes.
- In the setting of a more severe acute injury or avulsion, edema and ecchymosis are present and a defect may be palpated.
- The diagnosis of chronic groin pain is not as straightforward because of the broad spectrum of clinical entities that can cause pain in this region and their similar presentations.
- There is no current diagnostic gold standard for chronic groin pain.

FIG 1 • Muscle fibers forming the most lateral aspect of the adductor longus origin.
The differential diagnosis is critical owing to the possibility of other serious disorders; thus, a comprehensive history and physical is warranted in the patient with chronic groin pain.

The physical findings of chronic adductor pain are similar findings to those of an acute strain, but the examiner is more likely to elicit pain with palpation of the pubic symphysis and is more reliant on imaging, coupled with the examination, for a definitive diagnosis.

Involvement of the symphysis pubis detected by physical and even radiographic examination is common.

Chronic adductor-related pain often occurs in conjunction with athletic pubalgia. Sports hernias can present with complaints of vague and migratory lower abdominal pain radiating to the medial thigh.

Sports hernia findings are pain with a sit-up maneuver or resisted internal rotation of a flexed hip. Tenderness to palpation is found above the inguinal ligament and superior to the pubic tubercle. Tenderness may be more focal, involving the external inguinal ring without a palpable hernia or in the vicinity of the conjoint tendon.

Physical examination should include:
- Squeeze test. The presence or absence of pain is noted. Strength is graded as follows: mild—minimal loss of strength; moderate—clear loss of strength; severe—complete loss of strength. Pain with or without a strength deficit implies adductor-related groin pain.
- Passive stretch of adductors. Pain localized to the adductor implies adductor-related groin pain.
- Palpation of external inguinal ring. Pain in the absence of a palpable hernia implies a sports hernia.
- Sit-up against resistance. Adductor pain implies a concomitant or isolated sports hernia.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging studies are most effective when selected on the basis of a thorough history and physical examination.
- MRI is the imaging modality of choice to evaluate chronic adductor-related pain.
- Muscle strains have high T2 signal at the muscle–tendon junction, which can extend along the epimysium.
- Enthesopathy, an overuse injury, reveals signal change within the adductor origin and, often, the pubic marrow.
- We believe that osteitis pubis, ie, marrow changes within the pubis, is a radiologic sign rather than a diagnosis, because these changes are most often present in the setting of adductor-related symptoms.
- Robinson demonstrated that patient symptoms and MRI abnormalities within the pubis correlated significantly and reproducibly with symptomatic adductor enthesopathy or chronic myotendinous strain. Thus, pubic marrow changes should alert the clinician to consider an adductor or lower abdominal wall injury.
- Additionally, Cunningham demonstrated pubic marrow changes are frequently associated with adductor injury, but adductor enthesopathy is also commonly identified in the absence of pubic marrow changes. This suggests adductor dysfunction most likely precedes pubic marrow changes.

In addition to signal changes within the adductor origin, muscle tendon junction, or pubis, a secondary cleft sign may be present.

- Brennan et al defined the abnormal secondary cleft as an extension of the normal hyperintense signal seen within the central symphyseal cleft to a location lateral to the midline or inferior to the joint.
- The secondary cleft is best visualized on a coronal STIR image (FIG 2). This secondary cleft, like pubic marrow changes, is thought to be a consequence of prolonged traction on the pubic rami and common aponeurosis anterior to the symphysis.
- Chronic injury leads to a communication between the central and secondary clefs owing to a microtare or partial avulsion of the adductor longus from the pubis.

**DIFFERENTIAL DIAGNOSIS**

- Athletic pubalgia (sports hernia)
- Inguinal hernia
- Acetabular labral tear
- Hip arthritis
- Femoral neck stress fracture
- Hip synovitis
- Referred testicular pain
- Gynecologic pathology
- Coxa saltsans
- Iliopsoas strain
- Intra-abdominal disorders

**NONOPERATIVE MANAGEMENT**

- Adductor-related acute strains and overuse injuries are all initially managed with rest, ice, compression, and elevation (the RICE method) and a brief period of nonsteroidal anti-inflammatory drugs (NSAIDs). Differentiation between a strain and an enthesopathy is critical, because musculotendinous strains are managed much more aggressively with early, active therapy.
- Early on, active and passive range of motion without pain is initiated.
- Once full, painless range of motion has been achieved, a progressive strengthening regimen is started. Increased emphasis is placed on core stabilization and strengthening of the pelvic musculature.
- Resistance training consists predominantly of eccentric exercise for the hip and pelvic musculature.
Holmich et al\textsuperscript{5} demonstrated that an active strengthening and coordination program for the pelvic musculature was significantly better than conventional physical therapy in treating chronic athletic-related groin pain.

- Nonoperative therapy is completed with sport-specific training and eventual return to play.
- Early return to play is not advised because of the high risk of recurrent injury. Tyler et al\textsuperscript{14,15} showed the best predictor of a future groin strain was an adductor-to-abductor muscle strength ratio of less than 80%.
- Acute adductor avulsions are best managed with nonoperative means, despite reports of successful repair.\textsuperscript{8,11}
- Schlegel et al\textsuperscript{11} reported on 19 acute avulsions in NFL players, where those managed nonoperatively had good outcomes and a markedly shorter recovery time.
- Verall\textsuperscript{16} reported on a specific nonoperative regimen for sports-related groin pain with MRI-documented pubic stress changes. Twenty-seven athletes were rested for 12 weeks, followed by an active therapy regimen. When evaluated by return to sport criteria, outcomes were excellent.
  - However, results were satisfactory only if the criterion of ongoing symptoms was used, because nearly a third of individuals remained symptomatic during their second season post–nonoperative treatment.
  - Additionally, 26\% of these athletes were participating at a lower level of competition.
- Holmich et al\textsuperscript{5} reported on 23 of 29 athletes with chronic adductor-related groin pain returning to symptom-free play at 19 weeks as a result of an active therapy program. Long-term follow-up was not obtained, and these injuries were not stratified regarding strain versus enthesopathy versus avulsion.

**SURGICAL MANAGEMENT**

- Chronic adductor-related groin pain that has failed nonoperative measures, including an active therapy program focused on strengthening of the pelvic musculature and core stabilization, can be successfully treated with tenotomy of the adductor longus.\textsuperscript{1} Although adductor tenotomy previously was reserved for patients with spasticity, it clearly has a role in the management of chronic and disabling groin pain in the athlete. Tenotomy is performed as an isolated procedure or in conjunction with a sports hernia repair.
- Individuals suspected of having a concomitant sports hernia are referred to a general surgeon for definitive management.

**Preoperative Planning**

- Surgical planning consists primarily of an extensive history and physical examination to confirm that the pain is isolated to the adductor and that all appropriate nonoperative measures have been exhausted.
- Additionally, a confirmatory MRI revealing enthesopathy or chronic strain with associated pubic marrow changes or cleft sign is warranted.

**Positioning**

- The patient is placed in the supine position with the operative extremity in an abducted and externally rotated position (FIG 3). The adductor origin is easily palpated in this position. Only the ipsilateral groin is prepped and draped.

**Approach**

- The adductor longus is superficial and proximal to the adductor brevis and adductor magnus origins.
- A 3-cm incision is marked about 1 cm inferior and parallel to the inguinal crease. This incision is centered over the palpable tendinous mass.

**FIG 3** • The operative thigh is flexed, abducted, and externally rotated to provide excellent exposure and easy palpation of the adductor origin.

**OPEN ADDUCTOR LONGUS TENOTOMY**

- The skin is incised in line with the previous mark down to the underlying fascia (TECH FIG 1A). The fascia is incised in a similar fashion, parallel to the skin incision, revealing the underlying adductor longus proximal tendon.
- The tendon is readily identified, and care is taken to identify the medial and lateral borders, noting that the lateral aspect often is composed of muscle fibers without a true tendinous component.
- Once the borders are defined, the tendon is elevated from the underlying adductor brevis and divided with cautery about 1 cm from its pubic origin while protecting the underlying adductor brevis (TECH FIG 1B). Note that the undersurface of the adductor longus is entirely muscular.
- Remaining proximal also protects the anterior division of the obturator nerve as it runs its course along the anterior aspect of the adductor brevis.
- Although some have reported suturing the distal stump of the cut tendon to the overlying fascia, this is not necessary; no distal retraction or deformity has been encountered in our experience.
- The fascia is repaired with an absorbable suture, and the overlying skin is approximated.
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>Surgical release or tenotomy of the adductor longus has a role in sports medicine for chronic and recalcitrant adductor-related groin pain.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Concomitant pathology</td>
<td>Adductor-related groin pain often is associated with athletic pubalgia. A general surgery evaluation is warranted before considering an isolated adductor tenotomy.</td>
</tr>
<tr>
<td>Anatomy</td>
<td>Muscle fibers often make up the lateral 5 to 11 mm of the adductor longus origin. The presence or absence of these fibers must be confirmed to ensure a complete tenotomy is accomplished.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Immediate ambulation is permitted without assistive devices. Stretching is avoided until the incision has healed.
- Once the incision has healed, a progressive strengthening and stretching routine is initiated, with an emphasis on core stabilization.

OUTCOMES

- Akermark performed isolated adductor tenotomy in 16 athletes with chronic adductor-related groin pain. All patients reported significant improvement. Fifteen of 16 returned to sporting activities within 6 to 8 weeks, and 12 of 16 returned to competitive sports by 14 weeks. Only 10 athletes returned to full athletic competition; five returned to a reduced level of competition.
- As one might expect, patients had decreased isokinetic testing relative to the nonoperative side. However, these patients were reported to maintain functional sports activity despite the measured deficit.
- A definitive recommendation to proceed with adductor tenotomy is difficult, particularly in the high-performance athlete. Therefore, adductor tenotomy is reserved as a last-ditch effort to return the chronically disabled athlete to competitive sports with the possibility of participation at a reduced level of performance.
- Additional study investigating nonoperative and surgical intervention of adductor-related groin pain clearly is warranted.

COMPLICATIONS

- We suspect that persistent groin pain attributed to an incorrect diagnosis or an untreated concomitant sports hernia is the most prevalent complication from adductor-related surgery.

REFERENCES

DEFINITION
- Stretch-induced proximal hamstring injury is common among athletes.
- These injuries represent a continuum including strain at the musculotendinous junction (MTJ), partial tear of the tendon, or complete avulsion of the hamstring muscle complex from the ischial tuberosity.\(^1,9\)

ANATOMY
- The hamstring muscle group consists of three muscles: the biceps femoris (long and short heads); the semitendinosus; and the semimembranosus. All three muscles, except for the short head of the biceps femoris, originate from the ischial tuberosity of the pelvis.
- The biceps femoris and semitendinosus have a common origin.
- The hamstrings are biarticular muscles bridging the hip and knee.
- The proximal tendons of the biceps femoris and semimembranosus have been shown to extend for about 62% and 73%, respectively, of their muscle bellies.\(^9,11\)
- The sciatic nerve lies immediately lateral to the hamstring origin.

PATHOGENESIS
- Eccentric activation while under stretch, as seen in a flexed hip and extended knee when the hamstrings attempt to decelerate the leg during knee extension in high-speed sports-related activity, is thought to be the principal mechanism of injury.\(^2,21\)
- An additional, but rare, mechanism for hamstring injury is extreme stretch with an uncertain amount of muscle activation. This may occur in situations such as waterskiing or when the knee is extended and there is sudden hip flexion.\(^1,9,11,18\)

NATURAL HISTORY
- The natural history of these injuries varies considerably, with a more proximal injury resulting in a longer time for recovery to pre-injury status and a greater likelihood of surgical intervention due to the persistent and significant disability associated with hamstring avulsion.\(^1\)
- Partial or complete hamstring avulsions should not be confused with strain at the musculotendinous junction. Avulsions can be extremely disabling and, unlike strain at the musculotendinous junction, may warrant surgical intervention. Avulsions cause symptoms of weakness and loss of muscle control, especially during fast-paced running.
- Fortunately, most proximal hamstring injuries are strains at the musculotendinous junction that are best managed non-operatively. Strains most often occur in the biceps femoris, and the most common location is near the muscle–tendon junction. Recovery time has been correlated directly with the percentage of muscle involved by measuring the cross-sectional area or the longitudinal length of abnormal muscle signal on MRI.\(^1,5,13,20\)
- Injuries involving over 50% of the cross-sectional area result in a recovery period longer than 6 weeks, whereas normal imaging findings result in a recovery period of approximately 1 week.\(^13\)
- The greatest risk factor for injury to the hamstring muscle complex is a history of previous injury to the same place.\(^16,21\)
- Peterson\(^17\) reported the recurrence rate for hamstring injury to be 12% to 31%. Whether the reinjury is attributed to insufficient rehabilitation and early return to sport or the persistence of pre-existing risk factors, the treating physician must have the ability to assess the degree of injury, a knowledge of the reparative process of healing muscle, and an understanding of the rehabilitative and preventive measures for hamstring injury.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Proximal hamstring injury typically results in sudden onset of pain in the posterior proximal thigh during athletic competition or training.
- Severe injury, such as an avulsion, may present with a visible deformity, swelling, ecchymosis, and a palpable defect. Focal tenderness to palpation and pain on provocation with resisted knee flexion are consistent findings.
- With the patient lying prone and the hamstrings activated, palpation of proximal hamstring origin is undertaken.
  - A palpable defect implies proximal avulsion.
  - Pain without a defect suggests partial avulsion.
- Obvious increase in apparent hamstring flexibility of the injured extremity implies proximal avulsion.
- The current classification of muscle injuries identifies mild, moderate, and severe injuries, based on the degree of clinical impairment.
  - Mild muscle injury is minimal to no loss of strength, whereas moderate injury is a clear loss of strength.
  - Severe injury is the complete absence of muscle function. In severe injury, neurogenic symptoms may be present secondary to direct compression or a traction neuritis on the adjacent sciatic nerve.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs are useful in evaluating for a bony avulsion.
- MRI is the imaging of choice to confirm the existence of a muscle injury or avulsion, particularly when a discrepancy exists between the examiner’s findings and the patient’s symptoms.
In separate investigations Connell, Kouloris, Askling, and Slavotinek correlated rehabilitation time to the percentage of muscle involved by measuring the cross-sectional area or the longitudinal length of abnormal muscle signal on MRI. Kouloris stated injuries involving greater than 50% of the cross-sectional area resulted in a greater than 6 week recovery period, whereas normal imaging resulted in a recovery period of approximately 1 week.1,5,13,20 Schneider-Kolsky et al19 questioned the ability of MRI to predict rehabilitation time for minor and moderate injury. Despite a limitation of variable methods of rehabilitation, they concluded MRI to be useful in predicting the duration of convalescence for moderate and severe injury. Conversely, they determined clinical assessment to be slightly better than MRI for minor injury. Verall reported on a subset of patients with a clear clinical diagnosis of hamstring strain, but an MRI negative for muscle injury. Like Schneider-Kolsky’s findings, Verall reported patients with hamstring muscle strain injuries demonstrable by MRI had a poorer prognosis than those whose posterior thigh injury was not MRI-positive. Askling also demonstrated a correlation between the location of injury by MRI and time to recovery. He found longer recovery times for injuries in close proximity to the hamstring origin. In other words, the more cranial the injury the longer the recovery time. Interestingly, the prediction of recovery time was equally good using the point of highest pain on palpation, established within 3 weeks of the injury.

MRI is most useful in the setting of moderate or severe injury to predict recovery time based on injury location or percentage of involved muscle or to detect an avulsion imperceptible on physical exam due to a massive hematoma or swelling (FIG 1).

**DIFFERENTIAL DIAGNOSIS**
- Referred lower back pain (discogenic, arthropathy, etc.)
- Radiculopathy (HNP, spinal stenosis)
- Sciatica
- Tumor
- Piriformis syndrome
- Apophysitis
- Pelvic stress fracture

**NONOPERATIVE MANAGEMENT**
- The vast majority of proximal hamstring injuries involve strain at the musculotendinous junction and are managed with nonoperative measures focusing on restoration of flexibility and muscle strength.8,10
- Treatment of a proximal hamstring injury is predicated on the grade or severity of the injury and an understanding of the balanced progression of muscle regeneration and scar formation.10
- Proximal hamstring strains are typically treated with a few days of rest based on the grade of injury followed by early active and passive mobilization within the limits of pain.
- Ice and compression are useful adjuncts to diminish bleeding and inflammation as large hematomas may adversely influence scar formation.
- Sport specific training usually starts approximately 2 weeks post injury.
- If there is no improvement by 3 to 4 weeks, an MRI should be obtained.
- Once athletes return to their sports, they should continue an in-season strengthening and stretching program, as prevention of reinjury is critical due to the high rate of recurrence.2,6,17,21,22

**FIG 1** • A.B. Hamstring strain reveals increased T2 signal along the entire length of the left hamstrings, particularly along the musculotendinous junction, involving the biceps femoris and to a lesser degree the semitendinosus and semimembranosus. C. Surgical exposure reveals complete avulsion of the proximal tendon from the ischial tuberosity. (C: Courtesy of Gary Fetzer, MD, and Brad Nelson, MD, Minneapolis.)
Chapter 30 PROXIMAL HAMSTRING INJURY

REPAIR OF HAMSTRING COMPLETE AVULSION

The posterior femoral cutaneous nerve and its proximal branches are identified running deep to fascia down the back of the thigh obliquely crossing the long head of the biceps femoris.

- Branches of the posterior femoral cutaneous nerve are the inferior cluneals and perineals.
- The inferior cluneal nerves, three or four in number, turn upward around the lower border of the gluteus maximus.
- The perineal branches are distributed to the skin at the upper and medial side of the thigh.
- The inferior border of the gluteus maximus muscle is mobilized by dividing the posterior fascia and retracting the muscle superiorly in order to expose the ischial tuberosity and avulsed tendon stumps.
- Starting distally from normal anatomy, the sciatic nerve is identified lateral to the ischium.
- If required, a careful sciatic neurolysis is performed in chronic cases.
- Care is taken to identify and protect the branches to the semimembranosus.

The avulsed tendon stumps are identified and tagged with a grasping suture using a no. 2 high strength suture (TECH FIG 1A).

Mobilization of the tendon stumps and proximal musculature is carefully performed in order to minimize tension on the repair and limit the amount of knee flexion, if any, required to approximate the tendons to their origin on the lateral aspect of the ischial tuberosity. In chronic cases, a distal hamstring lengthening may be necessary.

If there is an adequate residual, proximal tendon stump, a direct repair is performed. Otherwise the repair is performed using suture anchors after clearing the soft tissue from the anatomic footprint on the ischial tuberosity (TECH FIG 1B).

If a tendon cannot be mobilized to its anatomic origin on the ischium other authors have reported tenodesing the tendon to the adjacent myotendinous complex.

The fascia and overlying skin are then approximated in separate layers.
POSTOPERATIVE CARE

- The knee is held in the minimal amount of flexion to limit tension on the repair for approximately 3 to 4 weeks.
- Range of motion is initiated thereafter in order to obtain a normal gait by 6 weeks post surgery.
- A progressive strengthening regimen is initiated after 6 weeks with a return to sports related activity no earlier than 3 months after surgery.

OUTCOMES

- Klingele\(^{13}\) reported on suture anchor fixation in 11 individuals (average age 41.5 years) with complete proximal avulsion injuries. There were 7 acute and 4 chronic (>4 weeks) injuries treated with a 78% return to sport by 6 months and a 91% satisfaction after a minimum 2 year follow-up. Varying degrees of hamstring mobilization and fractional lengthening were performed in the chronic cases. However, for patients who underwent repair of chronic injuries the average hamstring muscle strength was 89% of the uninjured extremity by Cybex testing at an average 34-month follow-up.
- Chakravarthy performed either direct or suture anchor repair in 4 patients, 1 acute and 3 chronic, with all patients obtaining normal strength and near-normal flexibility at an average 15 months of follow-up.\(^4\) Three of these four patients returned to their preinjury level of sport.
- Cross performed repairs on 9 patients (average age 34 years) with chronic, complete avulsions at an average of 36 months post injury.\(^7\) These patients were held at 90 degrees of knee flexion for 8 weeks after surgery with full knee range of motion obtained by 14 weeks in all cases. At an average 4 year follow-up, hamstring strength was 60% of the unaffected side with 7 of 9 patients having returned to a lower level of sports.
- Brucker performed surgical repair in 8 complete avulsions, 6 acute and 2 chronic, also immobilizing the operative extremity at 90 degrees of knee flexion for 6 weeks post surgery.\(^3\) Full range of motion was obtained in all patients by 16 weeks. At 33 months follow-up all patients were satisfied and 7 had returned to sports. The minimum time to return to sports was 6 to 8 months with 2 individuals delayed more than 24 months. Objective measures revealed no difference in hamstring flexibility relative to the contralateral extremity. Cybex dynamometer testing revealed an average peak torque of the operated hamstring muscles of 88.8% compared to the opposite limb.
- Orava described surgical intervention in 8 patients, 5 acute and 3 chronic, with complete or incomplete proximal avulsions using suture anchors, drill holes, or tenodesis of the avulsed hamstring to an adjacent and intact hamstring.\(^{15}\) Hip and knee flexion were avoided for 1 month with full weight bearing initiated at 1 month. All 5 acute patients exhibited normal strength and full range of motion at 5.7 year follow-up. However, those patients surgically treated 3 or more months from their injury had inferior outcomes.
- Lempainen recently described surgical repair of 48 MRI confirmed partial proximal hamstring avulsions or tendon tears in athletes who failed to respond to nonsurgical measures.\(^{14}\) Forty-three of these injuries were operated on more than 4 weeks from the time of injury with an average delay of 13 months. No immobilization was performed and full weight bearing was initiated at 2 weeks after repair. Eighty-eight percent of these patients reported good or excellent results and 87% returned to their preinjury level of sport at a mean follow-up of 36 months. However, this population predominantly consisted of patients who had failed conservative treatment. There are no reports on the number of patients successfully managed with nonoperative measures for partial avulsions.
Despite variable technique, degree of chronicity, and heterogeneous patient populations, these reports indicate repair of acute and chronic complete or partial proximal hamstring avulsion can improve patient outcomes. Early surgical intervention for complete tears is preferred in order to limit hamstring retraction and muscle atrophy and to obtain a better functional outcome. Whether or not surgical treatment should be considered in the acute setting for partial injuries remains unclear. The delay in return to sport and the persistent functional impairment associated with partial avulsions as reported by Sallay and Lempainen suggests further study is warranted regarding the indications and timing of surgical intervention in this population.

COMPLICATIONS

- Surgical repair of proximal hamstring avulsions have resulted in satisfactory outcomes; however, several authors have reported on several patients with persistent pain and/or spasm associated with strenuous exercise.
- Brucker reported on a loss of fixation for a single suture anchor from the ischial tuberosity. The anchor was removed in a second surgical procedure due to pain in a sitting position.
- Others have reported on persistent sciatica mandating a neurolysis to address postoperative scarring.

REFERENCES

Knee arthroscopy is a video-assisted surgical intervention for intra-articular disease of the knee.

**ANATOMY**

- The knee can be divided into three compartments: the patellofemoral joint, the lateral tibiofemoral joint, and the medial tibiofemoral joint.
- The patellofemoral compartment is composed of the suprapatellar pouch, the patella bone, its femoral articulation (called the trochlea), the medial and lateral femoral condyles, and the medial and lateral patellofemoral ligaments.
- The suprapatellar pouch is a potential space that develops when the knee joint is insufflated with fluid. Within this area, adhesions, plicae, and loose bodies may be found. Adhesions are commonly found with revision surgery.
- Synovial plicae are bands of synovium that are remnants from fetal development. Their location and size may contribute to snapping sensations and inflammation within the joint. In the suprapatellar pouch, however, they most commonly provide a location for loose bodies to hide.
- Suprapatellar plicae may partition an entire compartment within the pouch, leaving only a centralized hole by which loose bodies may gain entrance. These holes are called porta.
- The patella is one of the sesamoid bones of the body. It has a medial and a lateral facet that articulate with its respective condyles. Centrally, there is an apex of the bone that sits in the trochlea.
- The patella has the thickest cartilage in the body, which is used to withstand forces up to five times body weight.
- With normal articulation of the patella on the femur, the cartilage of the medial facet touches the medial femoral condyle. This can be visualized with arthroscopy.
- The patella begins to engage the trochlea at approximately 20 degrees and fully engages at 45 degrees. Lack of contact of the medial facet with the medial femoral condyle at these points in the range of motion suggests malalignment.
- The medial and lateral patellofemoral ligaments are thickenings of the medial and lateral retinaculum respectively. They originate centrally on the patella and insert onto the medial and lateral epicondyles of the femur.
- The medial patellofemoral ligament may become disrupted or attenuated with patellar dislocations. This may predispose to further dislocations, necessitating operative repair.
- The lateral patellofemoral ligament and retinaculum are often released in efforts to restore patellofemoral alignment.
- The medial tibiofemoral compartment is composed of the medial gutter and the tibiofemoral articulation.
- The medial gutter is a fold of synovium in the posteromedial aspect of the joint where loose bodies may hide. Ballooning of this space is essentially to ensure that no potential sources of pain exist within this region.
The popliteus tendon inserts onto the posterior body of the lateral meniscus and provides stability to the meniscal body. It attaches to the meniscus by means of three popliteomeniscal fascicles: the anteroinferior, posterosuperior, and posteroinferior fascicles. Anterior and posterior to the insertion of the tendon on the lateral meniscus is a recess of the joint capsule that does not insert onto the periphery of the meniscus. This makes the lateral meniscus more mobile than the medial meniscus.

Along the posterior horn of the meniscus originate two ligaments that insert into the femur. The ligament of Wrisberg travels posterior to the posterior cruciate ligament (PCL) to insert onto the femur; the ligament of Humphrey travels anterior to the PCL and inserts onto the femur.

Between the medial and lateral articulations is the intercondylar notch. It is a nonarticular portion of the knee that extends distally and posteriorly from the trochlea.

In the most anterior aspect of the notch lies the transverse meniscal ligament. This is a ligament that originates at the anterior horn of the medial meniscus away from the anterior root and inserts on the anterior horn of the lateral meniscus anterior to the anterior root of the lateral meniscus.

This space between the transverse ligament and the anterior horn of the medial and lateral menisci is often mistaken for a tear of the menisci on magnetic resonance imaging (MRI).

There is significant bony variation in terms of the width of the intercondylar notch; this may contribute to the decision to perform a notchplasty or notch widening when performing an anterior cruciate ligament (ACL) reconstruction.

The ACL and PCL reside within the intercondylar notch.

- The ACL originates at the posterolateral position (about 10:30 on a right knee and 1:30 on a left knee) of the inner wall of the notch and inserts centrally and anteriorly on the tibia. In the sagittal plane, it inserts slightly posterior to the anterior horn of the lateral meniscus and about 7 mm anterior to the PCL fibers.

- The PCL originates from the anterior aspect of the medial wall of the notch and has a broad origination that begins at about 12 o’clock and ends around 3:30 (on a right knee). This ligament travels posterior to the ACL and inserts centrally on the posterior aspect of the tibial plateau about 10 to 15 mm inferior to the joint line. The fibers run quite close to the posterior root of the medial meniscus and one must be careful not to deviate medially when débriding PCL remnants in this region during a PCL reconstruction.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- Each patient is unique and the equipment needed for each surgery will vary. The surgeon must review the case specifics and studies before surgery and ensure that all necessary equipment is available when the surgery begins.

- On the day of surgery, the surgeon should reconfirm with the patient the laterality of the procedure, “sign your site,” and verify that there has been no change in the signs and symptoms of the injury since the last office visit.

- The surgeon performs an examination under anesthesia to reconfirm the diagnosis because this is crucial to understanding the nature of the injury. With sedation, the patient is more relaxed and able to give a more sensitive examination.

**Positioning**

- The patient should be supine and close to the edge of the bed.

- The surgeon should verify that he or she will be able to get proper flexion of the leg should it be necessary to drop the foot of the bed.

- The contralateral leg can be placed in a well-padded leg holder or secured to the bed with circumferential padding.

- The use of a thigh holder versus a lateral post for arthroscopy is based on surgeon preference.

- The thigh holder can be used with the foot of the bed dropped to 90 degrees, or the leg may be abducted and brought over the side of the bed (Fig 2A).

- Commercial knee holders may not be capable of holding very large knees or pediatric knees. In these cases, a lateral post is preferred (Fig 2B).

**Approach**

- The approach largely depends on what arthroscopic knee procedure is going to be performed.

- Regardless, portal placement is the key to successful knee arthroscopy.
PORTAL PLACEMENT

- TECH FIG 1 shows the locations of the far lateral, anterolateral, anteromedial, and far medial portals and their relationships to landmarks of the knee.

Anterolateral Portal
- Most arthroscopic visualization is performed through this portal.
- It is created just lateral to the patella tendon. The incision is usually placed just inferior to the inferior aspect of the patella. Alternatively, the incision can also be referenced from the tibia.
- The incision should measure 1 cm long.
- Typically the incision is made vertically, but some surgeons prefer a horizontal incision, which may aid in preventing inadvertent laceration to the infrapatellar branch of the saphenous nerve.

Anteromedial Portal
- This is the primary working portal.
- Its position is highly dependent on the work that needs to be done.
- Traditionally, it is slightly more inferior than the anterolateral portal and just medial to the patella tendon, but the surgeon should be liberal about moving the location of this portal to optimize the surgical goals of the arthroscopy (ie, meniscal surgery versus mosaicplasty).
- The surgeon can use a spinal needle to localize the optimal portal placement before making the anteromedial portal incision.

Superomedial or Superolateral Portal
- A superior portal can be placed either medial or lateral to the quadriceps tendon.
- We prefer a superolateral portal because it results in less vastus medialis oblique inhibition.
- This portal can be used as an inflow or outflow portal or to perform procedures in the suprapatellar pouch (ie, loose body removal, medial retinaculum plication, synovectomy, or evaluation of patella tracking).
- This portal is placed about 2.5 cm proximal to the superior pole of the patella at the edge of the quadriceps tendon.

Central (Transpatellar) Portal
- This portal uses a vertical incision through the central third of the patellar tendon at the level of the joint line.
- It is mostly used to facilitate access to the intercondylar notch.

TECH FIG 1 • Artist’s rendition (A) and anterior view (B) of the right knee showing portal placement of far lateral, anterolateral, anteromedial, and far medial portals and their relationships to the inferior pole of the patella, the medial and lateral joint line, and the patellar tendon. C. Medial view of right knee showing anteromedial, far medial, and posteromedial portal placement and their relationships to the medial tibial plateau and medial femoral condyle. D. Lateral view of right knee far lateral, anterolateral, and posterolateral portal placement and their relationships to the lateral tibial plateau, lateral femoral condyle, fibula, and biceps tendon.
Occasionally, this portal may be required when performing a modified Gillquist maneuver (examination of the posterior horns of the menisci through the intercondylar notch) in a patient with a stenotic intercondylar notch.

**Posteromedial Portal**
- When pathology presents in the posteromedial knee, this portal may be used as a working portal.
- To assess the proper placement of this portal, the surgeon performs a modified Gillquist maneuver through the anterolateral portal (technique details are given in the Diagnostic Arthroscopy section) and uses the 70-degree arthroscope to transilluminate the skin overlying the posteromedial capsule.
  - A spinal needle is placed at the center of the transilluminated skin. This position should be about 1 to 2 cm above the joint line.
  - When comfortable with the position of the needle, the surgeon makes a 1-cm skin incision with a no. 11 blade and places a cannula with a blunt obturator to penetrate the capsule. This helps to protect the soft tissues in this area from damage and reduces fluid extravasation into the surrounding soft tissues.

  ![Tech FIG 2](https://example.com/techfig2.png)  
  *Arthroscopic view of the suprapatellar pouch showing adhesion running obliquely.*

**Posterolateral Portal**
- The indications and technique for this portal are similar to those for the posteromedial portal.
- The surgeon perform the modified Gillquist maneuver through the anterolateral portal and transilluminates the skin overlying the posterolateral capsule of the knee with the 70-degree arthroscope as described above.
- A spinal needle is used to confirm proper portal placement. This portal should be at the lateral aspect of the posterolateral compartment to avoid the large neurovascular structures.
- Before making the skin incision, the surgeon should ensure that the planned incision is anterior to the biceps tendon to avoid the peroneal nerve.

**Far Lateral and Far Medial Portals**
- These portals are made 2 cm either lateral or medial to their respective anterior portals.
- They can be used to aid in work that needs to be done posterior to the femoral condyles.

**Anterolateral Portal**
- Using a no. 11 blade knife, the surgeon places a vertically oriented 1-cm incision just lateral to the patellar tendon and inferior to the patella with the knee at 60 to 90 degrees of flexion.
- The bevel of the knife is buried (blade facing away from the meniscus) to ensure the capsule has been penetrated.
- The knife is angled toward the intercondylar notch to prevent damage to the lateral femoral condyle.

**Anteromedial Portal**
- Creation of an anteromedial portal is necessary to complete a thorough diagnostic arthroscopy.
- The surgeon may use a probe placed through this portal to palpate the cartilage for injury and perform a complete evaluation of the menisci once the arthroscope has been inserted.
- The position of this portal varies depending on the work being performed. Typically, it is 1 cm medial to the patellar tendon and slightly inferior to the anterolateral portal.

**Introduction of Obturator and Sheath**
- With the knee flexed at 60 to 90 degrees, the arthroscope sheath is placed with a blunt obturator through the anterolateral portal, aiming toward the intercondylar notch.
- Intra-articular position is confirmed by palpating the obturator anterior to the medial compartment.
- By dropping his or her hand, the surgeon pulls the obturator and sheath back slightly.
- As the knee is brought to an extended position, the obturator and sheath is gently advanced in the suprapatellar pouch.

**Visualization of Suprapatellar Pouch**
- The camera is placed in the suprapatellar pouch (Tech FIG 2).
- The size of the pouch is evaluated.
- The surgeon looks for adhesions and loose bodies.

**Visualization of the Patella**
- The camera is aimed anteriorly (toward the ceiling) to visualize the patella.
Assessment of Patellar Tracking
- The arthroscope is retracted further and the knee is ranged from flexion to extension to assess patellar tracking.
- The medial facet of the patella should engage the medial aspect of the trochlea at 20 degrees and fully engage in the trochlea at 45 degrees.
- Lateral facet overhang may suggest a tight lateral retinaculum and maltracking.

Lateral Gutter
- The arthroscope is advanced up into the suprapatellar pouch so the tip is proximal to the patella.
- With the patient's knee extended, the surgeon brings the arthroscope over the lateral femoral condyle. The surgeon's hand is raised so that the camera is angling down toward the floor, and the light source is turned so that it is looking distally (TECH FIG 4A).
- The lateral gutter (located between the lateral femoral condyle and the lateral capsule of the knee joint) will be visualized.
- By pushing posteriorly, the insertion of the popliteus tendon and its three popliteomeniscal fascicles of the lateral meniscus may be visualized (TECH FIG 4B,C).

Visualization of the Lateral Meniscocapsular Junction and the Anterior Knee
- The arthroscope is retracted to visualize the attachment of the lateral meniscus to the capsule. This is best performed with the knee in 20 degrees of flexion.

Visualization of the Trochlea and Condyles
- The arthroscope is aimed toward the femur, and the trochlea and anterior aspects of the medial and lateral femoral condyles are inspected.
- The probe is used to palpate the cartilage for evidence of softening, fissures, and unstable cartilage flaps.
- The arthroscope is retracted until the patella comes into view (TECH FIG 3).
- Pictures of the medial and lateral facets are taken.
- The surgeon's free hand can be used to mobilize the patella for better visualization.
- The cartilage of the patella is probed for evidence for softening, chondral flaps, or fissures.

Lateral Gutter
- The arthroscope is advanced up into the suprapatellar pouch so the tip is proximal to the patella.
- The lateral gutter (located between the lateral femoral condyle and the lateral capsule of the knee joint) will be visualized.
- By pushing posteriorly, the insertion of the popliteus tendon and its three popliteomeniscal fascicles of the lateral meniscus may be visualized (TECH FIG 4B,C).
A varus stress is applied to the knee at 30 degrees of flexion.

The lens of the arthroscope is turned medially to visualize the anterior horn of the lateral meniscus.

The anterior horn of the medial meniscus may also be seen more medially if the view is not blocked by synovium or the anterior fat pad.

**Medial Gutter**

The arthroscope is returned to the suprapatellar pouch, and then the surgeon migrates over the medial femoral condyle to the medial gutter.

By lifting his or her hand and aiming the light source so that the arthroscope is angling toward the floor again, the surgeon can visualize the medial gutter (space between the medial femoral condyle and the medial capsule of the knee joint).

Ballottement is performed to check for loose bodies.

A medial meniscal cyst and displaced meniscal flap tears may be visualized using this view as well.

**Medial Compartment**

From the medial gutter, the medial compartment is entered by bringing the arthroscope toward the midline until the medial femoral condyle is viewed (TECH FIG 5).

The knee is moved through a range of motion from full extension to full flexion. The entire medial femoral condyle is evaluated for cartilage defects.

The surgeon probes for softening, fissures, and flaps and checks for plica snapping over the condyle as well.

The posterior portion of the medial compartment is usually best visualized with the leg at 30 degrees, with a valgus stress applied to the knee.

The medial compartment may widen abnormally with valgus stress so that significant space between the medial tibial plateau and medial femoral condyle exists.

The surgeon should suspect a medial collateral ligament injury when this occurs. This is especially true if the meniscus lifts up off the tibial plateau, indicating significant tibial-sided medial collateral ligament laxity.

The tibial plateau is visualized and probed for chondral abnormalities. The surgeon should visualize the posterior root, posterior horn, body, anterior horn, and anterior root of the meniscus.

The undersurface of the meniscus is probed and inspected. The meniscus is tested with a hoop stress test.

The perimeter of the tibial plateau is probed for flipped flap tears of the meniscus.

In patients who are not ligamentously lax, the posterior horn periphery may be difficult to visualize.

In this case a modified Gillquist maneuver may allow better visualization of the posterior horn of the medial meniscus.

Instruments angled up work best in the medial compartment because the tibial plateau is a convex surface.

**Posteromedial Knee**

The surgeon performs the modified Gillquist maneuver.

The arthroscope is removed from the sheath and the blunt obturator is placed in the sheath. The knee should not be placed in 70–90 degrees of flexion.

The blunt obturator and sheath is placed into the anterolateral portal and advanced into the space between the medial aspect of the intercondylar notch and the posterior cruciate ligament (TECH FIG 6A).

Gentle pressure is applied until the obturator slides posteriorly.
The blunt obturator is replaced with the 70-degree arthroscope and camera, and the surgeon visualizes the posterior horn of the medial meniscus, the posterior medial femoral condyle, the posterior meniscal root and the capsular attachment, and the insertion of the PCL on the back of the tibial plateau (TECH FIG 6B). The surgeon can check for loose bodies as well.

**Intercondylar Notch**
- The leg is relaxed and allowed to dangle at the side of the bed.
- The cruciate ligaments are inspected in the intercondylar notch and their competency and laxity are tested (TECH FIG 7).

**Lateral Compartment**
- The arthroscope and probe can be situated in the intercondylar notch near the medial aspect of the lateral femoral condyle.
- The leg is placed in a figure 4 position with the knee flexed to 90 degrees while varus stress is applied. Ninety degrees of flexion is the optimal position for visualizing the posterolateral compartment of the knee.
  - When using a leg holder, varus stress can produce similar results.
- When the lateral compartment opens up so there is significant space between the lateral tibial plateau and lateral femoral condyle, the surgeon should suspect a posterolateral corner injury.
- The knee is moved through a range of motion from full extension to full flexion and the entire lateral femoral condyle and lateral tibial plateau are evaluated for cartilage defects (TECH FIG 8).

**Tech FIG 7** • Arthroscopic view of the intercondylar notch. The anterior cruciate ligament is well visualized on the left, with the posterior cruciate ligament on the right more obscured by fat and synovial tissue.

**Tech FIG 8** • Arthroscopic view of the lateral compartment, including the lateral femoral condyle, lateral tibial plateau, lateral meniscus, and popliteus tendon.

- The surgeon should probe for softening, fissures, and flaps.
- The meniscus is inspected and probed on its surface and undersurface.
- The popliteus tendon is checked for tears.
- The popliteal hiatus is checked for abnormal instability.
- The surgeon should visualize the posterior root, posterior horn, body, anterior horn, and anterior root of the meniscus.
- The undersurface of the meniscus is probed and inspected, and the meniscus is tested with a hoop stress test.
- The perimeter of the tibial plateau is probed for flipped flap tears of the meniscus.
- The surgeon should inspect the posterior horn of the lateral meniscus. This may require a variation of the modified Gillquist maneuver (mentioned previously).

**Modified Gillquist Maneuver for the Posterolateral Compartment**
- The arthroscope is removed from the sheath and the blunt obturator is placed in the sheath. The knee should not be placed in 70–90 degrees of flexion.
- The blunt obturator and sheath is placed into the anteromedial portal and advanced into the space between the lateral aspect of the intercondylar notch and the ACL.
- Gentle pressure is applied until the obturator slides under the ACL next to the lateral femoral condyle posteriorly to the posterolateral compartment.
- The blunt obturator is replaced with the 70-degree arthroscope and camera. The posterior horn of the lateral meniscus, the posterior lateral femoral condyle, the posterior meniscal root, and the capsular attachment are visualized. The surgeon can check for loose bodies as well.

**Pearls and Pitfalls**

- **Preoperative planning**
  - The surgeon should be sure to have all instruments and implants available that will be helpful to the surgery. A 70-degree arthroscope can be useful in most cases. Shoulder arthroscopy instrumentation and cannula systems can be helpful with more complex surgeries as well. The surgeon should talk to the patient before the surgery and perform an examination under anesthesia to confirm the pathology necessitating surgery.

- **Proper portal placement**
  - Surgical portal incisions should be tailored to the needs of the case. If a portal is not adequate or optimal, the surgeon should make a new portal. Larger or heavier patients may require larger portals for better maneuvering.
### POSTOPERATIVE CARE

- Once the procedure has ended, postoperative care has begun.
- Excess fluid is eliminated from the knee with suction.
- Although there is some variation in portal closure, we prefer a simple skin closure with a nonabsorbable monofilament suture.
  - Regardless of suture type or technique, the surgeon should obtain a tight closure.
- Intra-articular and portal injection of local anesthetic may help with postoperative pain management.
- Deep vein thrombosis prophylaxis may be accomplished with a compression dressing from the toes to the thigh, elevation, mobilization, and ankle pumps.
- Regardless of postoperative weight-bearing status, most patients will require crutches for mobility.
- Cryotherapy has been shown to improve pain scores after knee arthroscopy and is recommended.
- Motion and weight-bearing status are determined by the procedure performed and the patient’s needs.
- Pain control with narcotics will likely be necessary for the first few weeks.

### COMPLICATIONS

- Iatrogenic cartilage injury
- Nerve injury: saphenous nerve, peroneal nerve, femoral nerve, sciatic nerve
- Vascular injury
- Deep vein thrombosis
- Compartment syndrome
- Arthrofibrosis
- Reflex sympathetic dystrophy
- Persistent hemarthrosis

### REFERENCES

DEFINITION
- Synovitis is inflammation of the synovial membrane. The synovial lining undergoes hyperplasia, most prominent in rheumatoid arthritis. A mononuclear infiltration often makes up the sublining. Redundant synovial folds and villae may be present.
- Synovitis secondary to inflammatory conditions can lead to painful, swollen, and stiff knees.
- After medical management has been exhausted, surgery is indicated if the patient experiences continued pain, swelling, and mechanical symptoms.
- Conditions associated with knee synovitis include rheumatoid arthritis, pigmented villonodular synovitis (PVNS), synovial osteochondromatosis, psoriatic arthritis, osteoarthritis, lupus arthropathy, gout, synovial hemangiomas, plicae, intra-articular adhesions, fat pad fibrosis, postruumatic synovitis, hemophilic synovitis, and fibrous ligamentum muscosum.1–4,6,9,14,15

ANATOMY
- Synovial tissue is a specialized mesenchymal lining of joints.
- Normal synovium supplies nutrients for the articular cartilage and produces lubricants that bathe the joint surfaces to allow smooth gliding. It is a specialized mesenchymal tissue.
- Histologic hallmarks of chronic synovitis include hyperplasia of the intimal lining, lymphocyte infiltration, and blood vessel proliferation.
- Patients with chronic synovitis can have localized or diffuse disease, depending on their underlying condition. When localized, imaging studies such as magnetic resonance imaging (MRI) can help direct arthroscopy. With diffuse disease, it is vital to visualize all aspects of the knee.

PATHOGENESIS
- In chronic synovitis, the synovial lining undergoes hyperplasia, angiogenesis, and increased cellularity (inflammatory cells such as lymphocytes and macrophages).
- Rheumatoid arthritis is one of many immunoinflammatory diseases. It presents as an insidious onset of morning stiffness with multiple joint involvement. The synovitis that ensues is likely an acute autoantibody-mediated inflammatory response.
- PVNS is a proliferation of nodules and villi in the synovium of joints. Typically it is monoarticular, most commonly affecting the knee.
- Hemophilia is an X-linked deficiency of clotting factors, leading to bleeding of varying severity.
  - The knee is the most common site of hemarthrosis. The repeated hemarthroses can lead to a chronic, progressive synovial hyperplasia.

NATURAL HISTORY
- Repeated bouts of acute synovitis or chronically inflamed synovium can lead to chronic pain, limited range of motion, and ultimately joint degeneration and arthrosis.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A full personal and family history of rheumatologic and hematologic disorders should be elicited, including involvement of other joints and episodes of knee or other joint swelling in the past.
- The patient may have a history of recurrent swelling, pain, warmth, stiffness, and mechanical symptoms (FIG 1).
- Patients may have the stigmata of psoriasis or lupus.
- PVNS can cause mechanical symptoms such as locking, not unlike a meniscal tear. A palpable mass may be present.
- Intermittent symptoms are more common with localized PVNS; diffuse PVNS has more of a chronic presentation.
- In rheumatoid arthritis, the cervical spine is commonly involved and must be evaluated before surgical intervention. Also, the disease is often not limited to the musculoskeletal system: patients can also have vasculitis, subcutaneous nodules, and pericarditis.
- During the physical examination the surgeon should look for effusion, tenderness, warmth, mass, and synovial thickening.
  - Range of motion: Loss of flexion or extension may indicate arthrofibrosis.
  - Lachman test: assesses competence of anterior cruciate ligament
  - Posterior drawer test: assesses competence of posterior cruciate ligament
  - Varus stress test: assesses competence of lateral collateral ligament
  - Valgus stress test: assesses competence of medial collateral ligament
- Malalignment and ligamentous insufficiencies are noted and will likely preclude arthroscopic synovectomy, given their association with joint destruction.
- Joint aspiration can be therapeutic and diagnostic.
- Synovial fluid analysis should include documentation of fluid color (ie, brownish in PVNS, indicating recurrent...
bleeding), testing for rheumatoid factor, complement levels, cell count, Gram stain, culture, and crystal analysis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs are important to document the extent of joint destruction.
  - The surgeon should look for the characteristic rheumatologic signs of periarticular erosions and osteopenia.
  - Radiologic signs of PVNS and gout include cystic, sclerotic, or erosive lesions.
  - Synovial chondromatosis is often visible.
  - Advanced degenerative disease is associated with a poorer prognosis after arthroscopy.12
- MRI is helpful to assess the scope of joint involvement before surgery (FIG 2).
  - Nodular PVNS can be readily seen as low signal on both T1 and T2 images.

**DIFFERENTIAL DIAGNOSIS**
- Synovial disorders
- Infection
- Degenerative joint arthrosis

**NONOPERATIVE MANAGEMENT**
- Conservative treatment includes medical management of the underlying disease.
  - Oral anti-inflammatory medications may be used, as well as intra-articular corticosteroid injections.
  - Gentle physical therapy can aid in maintenance of range of motion.

**SURGICAL MANAGEMENT**
- Arthroscopic synovectomy allows the identification and management of synovial lesions that may be missed with open procedures and also allows re-evaluation after the index procedure with a low morbidity.7,13
  - For more chronic or recurring conditions such as rheumatoid arthritis or hemophilic synovitis, this surgery can reduce the severity of pain and dysfunction commonly associated with these pathologies. It can reduce the number of recurrences and may slow the progression of joint arthrosis.7

**Preoperative Planning**
- Preoperative flexion and extension cervical spine radiographs are necessary to rule out instability in rheumatoid patients.
- Appropriate medical clearance is necessary to keep perioperative complications to a minimum.
- General anesthesia rather than local anesthesia is recommended because the procedure can be lengthy. An epidural may also be used when medically indicated and may aid in postoperative pain relief. A Foley catheter may be used in anticipation of prolonged anesthesia.

**Positioning**
- The patient is placed supine and brought to the edge of the bed to ensure that the leg may be easily hung over the side.
  - An arthroscopic leg holder is not used because it may prohibit the use of the superomedial and superolateral portals.
  - A well-padded thigh tourniquet is placed high on the operative leg.
  - The contralateral leg is placed in a well-padded leg holder, flexing the hip and knee, with the hip in slight abduction. Compressive wrapping or sequential compression stockings should be used on the contralateral leg owing to the length of the procedure (FIG 3).
  - The foot of the bed is dropped, allowing the operative leg to hang free. The bed is also flexed to produce slight hip flexion, decreasing the chance of femoral nerve palsy that may be associated with excessive hip extension and leg traction.
An arthroscopic lateral post may be placed midthigh on the side of the operative bed.
- A suction canister trap should be set up for biopsy collection.

**Approach**
- Portals are marked on the skin; five or six are generally needed for a complete synovectomy (FIG 4).

**DIAGNOSTIC ARTHROSCOPY**
- The operative limb is exsanguinated and the tourniquet is inflated to 250 to 300 mm Hg (TECH FIG 1A).
- The procedure is begun with outflow in the superomedial portal because this is rarely used as a viewing portal (TECH FIG 1B).
- An incision is made in the inferolateral portal. The arthroscope is placed into the suprapatellar pouch with the knee in extension. A superolateral working portal is established (TECH FIG 1C,D).

**SYNOVECTOMY**

**Suprapatellar Pouch, Medial and Lateral Gutter, and Intercondylar Notch**
- With the arthroscope in the inferolateral portal, the shaver is placed in the superolateral portal. The synovium is resected from the suprapatellar pouch and the lateral gutter (TECH FIG 2A,B).
- The shaver is moved to the inferomedial portal. The synovium is excised from the medial gutter and the medial aspect of the suprapatellar pouch (TECH FIG 2C,D).
Retropatellar Pouch, Inferolateral and Inferomedial Gutters

- The arthroscope is moved to the superolateral portal and the shaver is placed in the inferolateral portal. This enables synovial resection from the inferolateral gutter and the retropatellar space (TECH FIG 3A,B).
- The shaver is placed in the inferomedial portal to complete the synovectomy of the retropatellar space and the inferomedial gutter (TECH FIG 3C,D).

Intercondylar Notch

- The arthroscope is returned to the inferolateral portal and the shaver is maintained in the inferomedial portal (TECH FIG 4A,B).
- Resection of synovium in the intercondylar notch and around the cruciate ligaments is carefully performed (TECH FIG 4C).
- This establishes adequate working space within the notch to allow visualization of the posterior compartments of the knee.
- Care must be taken to distinguish synovium from ligament.

**TECH FIG 3** • A. The arthroscope is moved to the superolateral portal, and the shaver is placed in the inferolateral portal. B. Arthroscopic view of the resection in the retropatellar space and lateral gutter. C. The arthroscope is moved to the inferomedial portal, and the shaver is placed in the inferolateral portal. D. Arthroscopic view of inferomedial gutter synovial resection.
Posteromedial Compartment

- For access to the posteromedial compartment, a blunt-tipped trocar is placed in its arthroscopic sheath and inserted through the inferolateral portal.
- Alternatively, a switching stick can be placed through the inferolateral portal under direct visualization with the arthroscope placed in the inferomedial portal.
- The medial femoral condyle is palpated with the tip and the trocar is pushed posteriorly in the interval between the medial femoral condyle and the posterior cruciate ligament, raising the hand to accommodate the posterior slope of the tibia.
- The trocar should push into the posteromedial compartment without too much force.
- If this proves difficult to accomplish, a central patellar tendon portal may allow easier access to the posterior compartment.

- The trocar is removed and the arthroscope is inserted. From this position, the posterior aspect of the medial femoral condyle and the posterior horn of the medial meniscus can be visualized.
- While looking medially, a posteromedial working portal is developed under direct visualization.
- A spinal needle is inserted anterior to the medial head of the gastrocnemius to avoid the neurovascular structures (TECH FIG 5A).
- Once in the appropriate position, a small, longitudinal incision is made through the skin.
- Using a hemostat, the soft tissue is spread until the capsule is reached.
- Using a blunt-tipped trocar and arthroscopic cannula, the hemostat is replaced to establish a working portal.
- The surgeon inserts the shaver after removing the trocar and proceeds with resection of the synovium in the posteromedial compartment (TECH FIG 5B,C).

**TECH FIG 4**

A. The arthroscope is returned to the inferolateral portal, and the shaver is in the inferomedial portal. B. Arthroscopic photograph shows the resection of synovectomy in the notch. C. Arthroscopic photo shows complete resection of synovium in the notch. The anterior cruciate ligament is now apparent.

**TECH FIG 5**

A. Arthroscopic photograph showing establishment of the posteromedial portal. B. Arthroscopic photograph showing placement of the arthroscope and shaver in the posteromedial compartment. C. Synovial resection in the posteromedial compartment.
Posterolateral Compartment

- With a blunt trocar in the arthroscopic cannula, the trocar is placed in the inferomedial portal.
- The lateral femoral condyle is palpated with the trocar and pushed along the notch between the condyle and the anterior cruciate ligament (TECH FIG 6A).
  - This can also be done with a switching stick, as described in the previous section.
  - Again, the hand is raised to accommodate the posterior slope of the tibial plateau.
- The trocar should give way, indicating passage into the posterolateral compartment. It is important not to push through any great resistance to avoid penetrating the capsule and damaging the neurovascular structures.
- The arthroscope is placed into the cannula. The posterior aspect of the lateral femoral condyle as well as the posterior horn of the lateral meniscus should be seen.
- A posterolateral portal is made by inserting a spinal needle into the compartment under direct visualization (TECH FIG 6B,C).
  - The needle should be inserted posterior to the fibular collateral ligament and anterior to the lateral head of the gastrocnemius.
  - The soft spot anterior to the biceps femoris muscle and posterior to the iliotibial tract will ensure protection of the peroneal nerve.

When making the posterolateral and posteromedial portals, the surgeon should make sure that the instruments can be directed in the coronal plane behind the corresponding femoral condyle.

- In a manner similar to the posteromedial portal, the skin is incised with a scalpel and the surgeon dissects to and then through the posterior capsule with a hemostat under direct visualization.
- Maintaining the same angle, the surgeon replaces the hemostat with a blunt trocar in an operative cannula.
- The surgeon inserts the shaver and proceeds with débridement of the posterolateral compartment (TECH FIG 6D,E).
- Hypertrophied synovium on the posterior capsule and posterior septum should be resected.
- The suction must be monitored carefully because the posterior capsule may be penetrated, placing the neurovascular structures at risk.
- After completion of the synovectomy, the tourniquet is released and hemostasis is achieved with electrocautery.
- The entire suction canister should be sent for pathology and microbiology testing (TECH FIG 6F).
- A suction drain is typically used for 24 hours postoperatively to minimize hemarthrosis.
- Light compressive dressing and cryotherapy are used to minimize swelling and encourage early joint motion.
Regaining and maintaining full knee range of motion and quadriceps function is critical. Cannulas should be used when possible to ensure atraumatic entry and exit of instruments, avoiding soft tissue injury.

At the end of the procedure, hemostasis must be obtained. Failure to do so may result in hemarthrosis and maintaining range of motion.

The surgeon must be prepared to view the knee from multiple portals.

Enough tissue must be obtained for pathologic evaluation and diagnosis.

Portals must be placed under direct visualization to protect neurovascular structures.

POSTOPERATIVE CARE

- The patient is weight bearing as tolerated.
- Continuous passive motion is advised in cases of complete synovectomy, advancing as tolerated over 1 to 3 days.
- Physical therapy is initiated after removal of the suction drain. Closed-chain exercises are emphasized.

OUTCOMES

- When comparing arthroscopic synovectomy to open synovectomy, the arthroscopic technique is associated with lower morbidity and more rapid return of function and lower rates of recurrence in rheumatoid, hemophilia, and other inflammatory arthropathies. In addition, synovectomy can be more complete with accurate visualization of the posterior compartments.
- One study of 96 rheumatoid arthritic knees found significant decreases in pain and synovitis at an average of 4 years after arthroscopic synovectomy.
- Along with the use of rheumatoid medications, arthroscopic synovectomy can reduce inflammation and help preserve range of motion.
- Success rates in the relief of pain and swelling have been as high as 80% in the treatment of rheumatoid arthritis.
- Arthroscopic synovectomy has been used successfully in the treatment of PVNS.
- In the past, open synovectomies led to stiffness and pain after the procedure. In a series of 18 patients with diffuse PVNS, one third of the patients had a recurrence after open synovectomy, and in most patients the knee was manipulated in an attempt to decrease stiffness.
- Recurrence rates with arthroscopic synovectomy of PVNS have been as low as 11%, with improved range of motion.
- Localized PVNS has responded best to arthroscopic treatment.
- Multiple series have reported no recurrences at follow-up after excision of the lesion.
- The procedure allows improved visualization of lesions and facilitates the discovery of small, localized forms of PVNS.
- Hemophilic synovitis, also associated with aggressive joint destruction, has responded well symptomatically to arthroscopic synovectomy.
- Unlike most forms of synovitis, this usually requires a short period of hospitalization because of the underlying systemic disorder.
- The procedure has been effective in reducing recurrent hemarthrosis and maintaining range of motion.

However, joint deterioration continues to occur, although probably at a slower rate.

COMPLICATIONS

- Recurrent hemarthrosis, often requiring repeat aspirations or surgical irrigation and débridement
- Loss of range of motion
- Joint stiffness and flexion contracture can be challenging to treat.
- Dynamic bracing can be used.
- Rare complications include infection, either superficial or intra-articular, neurovascular injury, rapid onset of joint arthrosis, or cruciate ligament damage.

REFERENCES

DEFINITION

- Irreparable meniscal tears are those for which no healing response is possible.
  - This may include all or part of a meniscus, prompting partial, subtotal, or total meniscectomy.
- Meniscal injuries in the “white zone” (central avascular portion; FIG 1) most often require partial meniscectomy.
  - This usually involves the inner two thirds of the meniscus.
- Symptomatic tears of discoid lateral menisci also may require partial or subtotal saucerization of the meniscus.
- Numerous classifications of tears of the meniscus have been proposed based on location or type of tear, etiology, and other factors; most of the commonly used classifications are based on the type of tear found at surgery (FIG 2).
  - Longitudinal tears
  - Transverse and oblique tears
  - A combination of longitudinal and transverse tears
  - Tears associated with cystic menisci
  - Tears associated with discoid menisci
- The most common type of tear is the longitudinal tear, usually involving the posterior segment of either the medial or lateral meniscus.
- More lateral meniscal tears have been diagnosed than medial tears.
  - Although no definitive study comparing the incidence of medial to lateral tears has been reported, the two types are believed to occur with almost equal frequency.
  - Most partial-thickness tears involve the inferior rather than the superior surface of the meniscus.

- Certain patterns of meniscal tears are associated with mechanical locking.
  - Small longitudinal tears limited to the posterior horn usually are not capable of producing locking but rather cause pain, recurrent swelling, and subjective instability.
  - Extensive longitudinal tears can cause locking by displacing into the intercondylar notch.
  - A pedunculated fragment may result if either the posterior or anterior attachment of the bucket-handle fragment becomes detached.
- Transverse, radial, or oblique tears can occur in either meniscus but are more common in the lateral, usually at the junction of the anterior and middle thirds.
- Transverse tears also can result from degenerative changes that make the meniscus less mobile.
- Complex transverse and longitudinal tears may occur with degeneration or repeated traumatic episodes.
- Meniscal cysts frequently are associated with tears and are nine times more common on the lateral than on the medial side.
- Discoid menisci are abnormal in terms of both mobility and tissue bulk, making them vulnerable to compression and rotary stress.

ANATOMY

- The menisci are crescents that are roughly triangular in cross section.
- They cover one half to two thirds of the articular surface of the corresponding tibial plateau.
- They are composed of dense, tightly woven collagen fibers arranged in a pattern providing great elasticity and ability to withstand compression.
  - The major orientation of collagen fibers in the meniscus is circumferential.
  - Radial fibers and perforating fibers also are present (FIG 3A).
  - The arrangement of these collagen fibers determines to some extent the characteristic patterns of meniscal tears (FIG 3B,C).
- When meniscal samples are tested by applying a force perpendicular to the fiber direction, the strength is decreased to less than 10% because collagen fibers function primarily to resist tensile forces along the direction of the fibers.4
  - The circumferential fibers act in a similar manner as metal hoops placed around a pressurized wooden barrel; the tension in the hoops keeps the wooden staves in place (FIG 3D,E).
  - Hoop tension is lost when a single radial cut or tear extends to the capsular margin.
- The peripheral edges of the menisci are convex, fixed, and attached to the inner surface of the knee joint capsule, except where the popliteus is interposed laterally; the peripheral edges also are attached loosely via coronary ligament to the borders of the tibial plateaus.
- The inner edges are concave, thin, and unattached.
The menisci are largely avascular except near their peripheral attachment.

The inferior surface of each meniscus is flat, whereas the superior surface is concave, corresponding to the contour of the associated bony anatomy.

The medial meniscus is a C-shaped structure larger in radius than the lateral meniscus, with the posterior horn being wider than the anterior (FIG 4).6

The anterior horn is attached firmly to the tibia anterior to the intercondylar eminence and to the anterior cruciate ligament (ACL).

Most of the weight is borne on the posterior portion of the meniscus.

The posterior horn is anchored immediately in front of the attachments of the posterior cruciate ligament posterior to the intercondylar eminence.
Its entire peripheral border is firmly attached to the medial capsule and through the coronary ligament to the upper border of the tibia.

The lateral meniscus is more circular in form, covering up to two thirds of the articular surface of the underlying tibial plateau.

The anterior horn is attached to the tibia medially in front of the intercondylar eminence.

The posterior horn inserts into the posterior aspect of the intercondylar eminence and in front of the posterior attachment of the medial meniscus.

The posterior horn often receives anchorage also to the femur via the ligament of Wrisberg and the ligament of Humphrey and from fascia covering the popliteus muscle and the arcuate complex at the posterolateral corner of the knee.

The inner border, like that of the medial meniscus, is thin, concave, and free.

The tendon of the popliteus muscle separates the posterolateral periphery of the lateral meniscus from the joint capsule and the lateral collateral ligament. This tendon is enveloped in a synovial membrane and forms an oblique groove on the lateral border of the meniscus.

The lateral meniscus is smaller in diameter, thicker in periphery, wider in body, and more mobile than the medial meniscus.

The menisci follow the tibial condyles during flexion and extension, but during rotation they follow the femur and move on the tibia (FIG 5).

Consequently, the medial meniscus becomes distorted.

Its anterior and posterior attachments follow the tibia, but its intervening part follows the femur; thus, it is likely to be injured during rotation.

However, the lateral meniscus, because it is firmly attached to the popliteus muscle and to the ligament of Wrisberg or of Humphrey, follows the lateral femoral condyle during rotation and therefore is less likely to be injured.

In addition, when the tibia is rotated internally and the knee flexed, the popliteus muscle, by way of the arcuate ligament complex, draws the posterior segment of the lateral meniscus backward, thereby preventing the meniscus from being caught between the condyle of the femur and the plateau of the tibia.

The vascular supply to the medial and lateral menisci originates predominately from the lateral and medial geniculate vessels (both inferior and superior).

Branches from these vessels give rise to a perimeniscal capillary plexus within the synovial and capsular tissue, which supplies the peripheral border of the meniscus throughout its attachment to the joint capsule.

These vessels are oriented in a predominantly circumferential pattern, with radial branches directed toward the center of the joint.

Arnoczky and Warren\(^3,4\) used microinjection techniques to show that the depth of peripheral vascular penetration is 10% to 30% of the width of the medial meniscus and 10% to 25% of the width of the lateral meniscus.

The medial geniculate artery, along with a few terminal branches of the medial and lateral geniculate artery, also supplies vessels to the menisci through the vascular synovial covering.

The menisci have several proposed functions in the knee joint.

They act as a joint filler, compensating for gross incongruity between the femoral and tibial articulating surfaces.

They are believed to have a joint lubrication function, distributing synovial fluid and aiding the nutrition of the articular cartilage.

![FIG 4 • Superior view of tibial condyles. Lateral meniscus is smaller in diameter, thicker about its periphery, wider in body, and more mobile than the medial meniscus; posteriorly it is attached to the medial femoral condyle by either the anterior or posterior meniscofemoral ligament, depending on which is present, and to the popliteus muscle.](image)

![FIG 5 • Kinematics of the menisci with knee flexion, extension, and rotation. Although the lateral meniscus and lateral tibial plateau have a smaller AP width, the lateral meniscus moves more than the medial meniscus through each range of motion. (Adapted from Tria AJ Jr, Klein KS. An Illustrated Guide to the Knee. New York: Churchill Livingstone, 1992.)](image)
The menisci are also at increased risk in the presence of joint incongruities, ligamentous instability, profound muscle weakness, or congenitally relaxed joints.

As the knee is internally rotated during flexion, the medial meniscus is forced posteriorly. If the peripheral attachment stretches or tears, the posterior part of the meniscus is forced centrally, caught between the femur and tibia, and torn longitudinally as the knee extends.

If this longitudinal tear extends anteriorly beyond the medial collateral ligament, the inner segment of the meniscus is caught in the intercondylar notch and cannot return to its former position; thus, a classic bucket-handle tear with locking of the joint is produced (FIG 6).

The menisci are also at increased risk in the presence of joint incongruities, ligamentous instability, profound muscle weakness, or congenitally relaxed joints.

As the knee is internally rotated during flexion, the medial meniscus is forced posteriorly. If the peripheral attachment stretches or tears, the posterior part of the meniscus is forced centrally, caught between the femur and tibia, and torn longitudinally as the knee extends.

If this longitudinal tear extends anteriorly beyond the medial collateral ligament, the inner segment of the meniscus is caught in the intercondylar notch and cannot return to its former position; thus, a classic bucket-handle tear with locking of the joint is produced (FIG 6).

The same mechanism can produce a posterior peripheral or a longitudinal tear of the lateral meniscus.

Because of its mobility and structure, the lateral meniscus is not as susceptible to bucket-handle tears, but incomplete transverse tears are more common here than in the medial meniscus.

NATURAL HISTORY

The effects of meniscectomy on joint laxity have been studied for anteroposterior and varus-valgus motions and rotation.

These studies indicated that the effect on joint laxity depends on whether the ligaments of the knee are intact and whether the joint is bearing weight.

In the presence of intact ligamentous structures, excision of the menisci produces small increases in joint laxity.

When combined with ligamentous insufficiency, these increased instabilities caused by meniscectomy are greatly exaggerated.

In an ACL-deficient knee, medial meniscectomy has been shown to increase tibial translation by 58% at 90 degrees, whereas primary anterior and posterior translations were not affected by lateral meniscectomy.

Anatomically, the capsular components that attach the lateral meniscus to the tibia do not affix the lateral meniscus as firmly as they do the medial meniscus.

These results indicate that in contrast to the medial meniscus, the lateral meniscus does not act as an efficient posterior wedge to resist anterior translation of the tibia on the femur.

Therefore, in knees that lack an ACL, the lateral meniscus is subjected to different forces than those that occur on the medial side.

Allen et al,2 in a biomechanical study, determined that force in the medial meniscus increased significantly in response to an anterior tibial load after ACL transection, which may
account for some of the differences in injury patterns between the medial and lateral menisci in the anterior cruciate-deficient knee.

- Walker and Erkman noted that under loads of up to 150 kg, the lateral meniscus appeared to carry 70% of the load on that side of the joint, whereas on the medial side the load was shared about equally by the meniscus and the exposed articular cartilage.
- Medial meniscectomy decreases contact area by 50% to 70% and increases contact stress by 100%.
- Lateral meniscectomy decreases contact area by 40% to 50% but dramatically increases contact stress by 200% to 300% because of the relative convex surface of the lateral tibial plateau.
- Presumably the menisci provide mediolateral stability where the load is supported by the entire width of the tibial articular surface. Without the menisci the load is supported centrally on each plateau, diminishing the lever arm of load support.
- Radiographic changes apparent after meniscectomy include narrowing of the joint space, flattening of the femoral condyle, and formation of osteophytes.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Mechanical symptoms, such as catching, popping, and locking, usually occur only with longitudinal tears and are much more common with bucket-handle tears, usually of the medial meniscus.
- Locking of the knee is not pathognomonic of a bucket-handle tear of a meniscus: other conditions such as loose body, patellar maltracking, and intra-articular tumor can cause similar findings.
- The following clues can be important in the differential diagnosis:
  - Sensation of giving way
  - Effusion
  - Atrophy of the quadriceps
  - Tenderness over the joint line (or the meniscus)
  - Reproduction of a click by manipulative maneuvers during the physical examination
  - Probably the most important physical finding is localized tenderness along the posteromedial or posterolateral joint line, which is most commonly caused by reactive synovitis.
- A history of specific injury may not be obtained, especially when tears of abnormal or degenerative menisci have occurred.
- A patient without locking typically gives a history of several episodes of trouble referable to the knee, often resulting in effusion and a brief period of disability but no definite locking.
- A sensation of giving way or snaps, clicks, catches, or jerks in the knee may be described, or the history may be even more indefinite, with recurrent episodes of pain and mild effusion in the knee and tenderness in the anterior joint space after excessive activity.
- The injured knee should be compared with the opposite knee, which can exhibit 5 to 10 degrees of physiologic recurvatum. In this case, the injured knee can be locked and still extend to neutral position.
- Regardless of its cause, locking that is unrelieved after aspiration of the hemarthrosis and a period of conservative treatment may require surgical treatment.

- A serious error would be failure to distinguish locking from false locking.
- False locking occurs most often soon after an injury in which hemorrhage about the posterior part of the capsule or a collateral ligament with associated hamstring spasm prevents complete extension of the knee.
- Aspiration and a short period of rest until the reaction has partially subsided usually will differentiate locking from false locking of the joint, and magnetic resonance imaging (MRI) can confirm the diagnosis.
- A sensation of giving way is often present but is not specific to meniscal tear.
- Effusion indicates that something is irritating the synovium; therefore, it has limited specific diagnostic value.
- The sudden onset of effusion after an injury usually denotes a hemarthrosis, and it can occur when the vascularized periphery of a meniscus is torn.
- Tears occurring within the body of a meniscus or in degenerative areas may not produce a hemarthrosis.
- Repeated displacement of a pedunculated or torn portion of a meniscus can produce sufficient synovial irritation to produce a chronic synovitis with an effusion of a nonbloody nature.
- The absence of an effusion or hemarthrosis does not rule out a tear of the meniscus.
- Atrophy of the musculature about the knee suggests a recurring disability of the knee but does not indicate its cause.
- Clicks, snaps, or catches, either audible or detected by palpation during flexion, extension, and rotary motions of the joint, can be valuable diagnostically, and efforts should be made to reproduce and accurately locate them.
- Numerous manipulative tests have been described, but the McMurray test is most commonly used. Although other tests cannot be considered diagnostic, they are useful enough to be included in the routine examination of the knee.
- For the McMurray test, with the knee completely flexed, the examiner palpates the joint line with one hand and uses the other hand to rotate the foot internally while extending the knee. The maneuver is repeated with the foot externally rotated. If a meniscal tear is present, a click may be heard or felt in the joint line of the affected side during this maneuver.
- The grinding test, as described by Apley, is another test for isolating meniscal pathology. With the patient prone, the knee is flexed to 90 degrees and the anterior thigh is fixed against the examining table. Traction on the foot is used to distract the joint and the foot is rotated. Next, with the knee in the same position, the foot and leg are pressed downward and rotated as the joint is slowly flexed and extended.
- Another useful test, the squat test, consists of several repetitions of a full squat with the feet and legs alternately fully internally and externally rotated as the squat is performed. Reproduction of pain on the medial or lateral side of the knee is suggestive although not diagnostic of meniscal tear.
- The diagnosis of internal derangement of the knee caused by a meniscal tear can be difficult to make even for an experienced orthopedic surgeon, but a careful history and physical examination combined with appropriate imaging studies help to limit errors in diagnosis and unnecessary arthroscopy.
During an injury, damage to other structures of the knee such as the ligaments and articular cartilage is common. For simplicity, tears of the menisci are discussed here as though they were isolated injuries, but evidence of other injuries always must be sought.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Imaging includes standing anteroposterior, 45-degree posterior, and patellofemoral views to exclude other causes of knee pain such as joint degeneration, loose bodies, and osteochondritis dissecans.
- Other noninvasive diagnostic studies, such as ultrasonography, scintigraphy, computed tomography (CT), and MRI, have been shown to improve diagnostic accuracy in many knee disorders.
- Compared with arthroscopy, MRI has been shown to have 98% accuracy for medial meniscal tears and 90% for lateral meniscal tears.
- Others have reported that MRI had a positive predictive value of 73%, a negative predictive value of 90%, a sensitivity of 83%, and a specificity of 84% for pathologic changes in the menisci.
- MR arthrography may be useful in evaluating knees with prior meniscectomy or meniscal repair.
- High-resolution CT has been reported to have a sensitivity of 96.5%, specificity of 81.3%, and accuracy of 91%, but we usually use this study to evaluate the patellofemoral joint.

**DIFFERENTIAL DIAGNOSIS**
- Ligament injury
- Chondral injury
- Osteochondral loose body
- Pathologic plica
- Patellar maltracking
- Intra-articular tumor

**NONOPERATIVE MANAGEMENT**
- An incomplete meniscal tear or a small (5-mm) stable peripheral tear with no other pathologic condition, such as a torn ACL, can be treated nonoperatively with predictably good results. Many incomplete tears will not progress to complete tears if the knee is stable.
- Small stable peripheral tears have been observed to heal after 6 to 8 weeks of protection.
- Stable vertical longitudinal tears, which tend to occur in the peripheral vascular portions of the menisci, have been reported to heal with nonoperative treatment.
- Meniscal tears that cause infrequent and minimal symptoms can be treated with rehabilitation and restricted activity.
- Tears associated with ligamentous instabilities can be treated nonoperatively if the patient defers ligament reconstruction or if reconstruction is contraindicated.
- Nonsurgical management consists of activity modification, nonsteroidal anti-inflammatory, and physical therapy.
- If symptoms recur after a period of nonoperative treatment, surgical repair or removal of the damaged meniscus may be necessary.
- The most important aspect of nonoperative treatment, once the acute pain and effusion have subsided, is restoration of the normal knee range of motion and muscle strength. This can be accomplished through a regular program of progressive exercises to include the quadriceps, hamstrings, hip flexors, and hip abductors.

**SURGICAL MANAGEMENT**
- Indications for surgical treatment of meniscal tears include:
  - Symptoms that affect sports participation or activities of daily living or work (locking, giving way, frequent effusions)
  - Failure of nonoperative treatment
  - Absence of other causes of knee pain (based on complete clinical and imaging evaluations)
- Meniscectomy is categorized into three types depending on the amount of meniscus removed:
  - Partial meniscectomy, in which only loose, unstable meniscal fragments are excised and a stable and balanced peripheral rim of healthy meniscal tissue is preserved (FIG 7)
  - Subtotal meniscectomy, in which the type and extent of the tear require excision of a portion of the peripheral rim, usually leaving most of the anterior horn and a portion of the middle third intact
  - Total meniscectomy
- Historically, the indications and surgical techniques for excision of torn menisci have been controversial.
  - Some have advocated total excision of torn menisci, whereas others have proposed subtotal excision.
  - Justification for total excision often was based on short-term, functional recovery criteria; however, longer follow-up showed associated degenerative changes.
  - Removal of even one third of the meniscus has been shown to increase joint contact forces by up to 350%.
  - The amount of degenerative change in the articular cartilage appears to be directly proportional to the amount of meniscus removed.
- If meniscal pathology produces almost daily symptoms, frequent locking, or repeated or chronic effusions, the pathologic portion of the meniscus should be removed because the problems caused by the present disability far outweigh the probability or significance of future degenerative arthritis.
  - If a significant portion of the peripheral rim can be retained by subtotal meniscal excision, the long-term result is improved.
  - Partial meniscectomy by arthroscopic technique has sufficient support and clinical results to indicate its routine use.
  - Subtotal meniscectomy is justified only when it is irreparably torn, and the meniscal rim should be preserved if at all possible.
  - Total meniscectomy is no longer considered the treatment of choice in young athletes or other people whose daily activities require vigorous use of the knee.

**FIG 7** Partial meniscectomy: loose unstable fragments are excised and a stable and balanced peripheral rim of healthy meniscal tissue is preserved.
Preoperative Planning
- A discussion regarding meniscal repair versus removal should be conducted preoperatively. The patient should understand the risks, benefits, alternatives, and potential complications of both, as well as the variations in postoperative recovery time and rehabilitation.
- The patient also should understand the potential for recurrent meniscal tear and long-term consequences of meniscectomy.
- A discussion also should be held about the treatment of additional pathology, such as chondral lesions, that may be a source of continued symptoms postoperatively.
- The necessary equipment should be present to treat whatever meniscal or chondral pathology might be encountered.

Positioning
- The patient is placed supine with the nonoperative leg in a leg holder that brings the extremity into flexion at the hip and knee (FIG 8A).
- The use of a proximal leg holder for the operative knee places the patient’s foot on the surgeon’s iliac crest, eliminating the need for an assistant to hold the leg.

Approach
- After an examination under anesthesia, joint lines and soft tissue and bony landmarks are drawn on the skin before joint distention (FIG 8B).
- Typically, these are the outlines of the patella and patellar tendon, the medial and lateral joint lines, and the posterior contours of the medial and lateral femoral condyles.
- Standard and optional arthroscopic portals are marked (see Chap. SM-31).
- A small outflow, needle-type cannula can be placed superomedially or superolaterally, with inflow through the arthroscope, but this often is not needed for meniscectomy.
- A two-portal or three-portal technique can be used (see Chap. SM-31).
- The anterolateral and anteromedial portals are most commonly used with the two-portal technique.
- Occasionally, a posteromedial, accessory medial, or central portal is used to assist in removal of displaced meniscal fragments.
- Thorough, systematic arthroscopic examination of the knee joint must be done before the decision is made for partial or subtotal meniscectomy (see Chap. SM-31).
- An arthroscopic probe should be used to examine the meniscal tear to determine its anterior and posterior extents (FIG 8C). The probe should be used to palpate the superior and inferior extents of the meniscus.
- When an irreparable meniscal tear is identified, all mobile fragments that can be pulled past the inner margin of the meniscus into the joint should be removed and the remaining meniscus contoured to reduce the risk of leaving a defect that can propagate into a larger tear.
- The meniscal rim does not need to be perfectly smooth, and the amount of meniscus removed and contouring of the rim must be weighed against the risk of degenerative changes (the risk of degenerative changes is directly proportional to the amount of meniscus removed).
- The goal is to remove the tear entirely while removing as little meniscus as possible.

ARThROSCOPIC PARTIAL MENISCETOMY FOR CONVENTIONAL TEARS
- The goals of surgery are to remove the mobile segment at the meniscal base and to contour the remaining meniscus to leave as wide a rim as possible.
- Any tags or pieces of meniscus that may catch in the joint or can be displaced into the center of the joint are resected with meniscal forceps, baskets, scissors, or graspers (TECH FIG 1).
- Full-radius resectors and motorized suction shavers are used to remove damaged cartilage, smooth the meniscal rim, and remove loose pieces of meniscus and cartilage.
- Various ablation devices can be used to contour tears; however, care must be taken not to damage adjacent articular cartilage.
- For horizontal cleavage tears, one or both “leaves” can be resected, depending on surgeon preference. No definitive study has shown that preserving either the superior or inferior leaf improves results.
ARTHROSCOPIC PARTIAL MENISCECTOMY FOR BUCKET-HANDLE TEARS

- A probe or blunt trocar is used to reduce the fragment to its normal position (TECH FIG 2A).
- Partial division of the posterior attachment of the meniscal fragment is done with basket forceps, scissors, or an arthroscopic knife. The cut should go almost completely through the posterior attachment of the mobile fragment at its junction with the remaining normal meniscal rim (TECH FIG 2B).
- To avoid damage to the normal meniscus or articular cartilage, this cut should not be made blindly. Exposure can be aided by passing the arthroscope through the intercondylar notch to view the posterior horn of the meniscus while cutting. Alternatively, a posteromedial portal can be made for direct observation.
- A small tag of meniscal tissue is left intact posteriorly to prevent the meniscus from becoming a loose body in the joint after anterior release.
- The anterior horn attachment is divided with angled scissors, basket forceps, or an arthroscopic knife. The release should be made flush with the intact anterior rim so that no stump or dog-ear remains (TECH FIG 2C).
- If access to the anterior horn attachment is difficult through the ipsilateral portal, changing portal sites and approaching from the contralateral portal with the
instrument often makes this easier. Rarely, a midpatellar portal is necessary so that both anterior portals can be used for instruments.

- A hemostat is used to enlarge the capsular incision before attempting meniscal removal.
- A grasping clamp is inserted through the ipsilateral portal to grasp the meniscal fragment as close to its remaining posterior attachment as possible. With the fragment in view, the grasping forceps are twisted and rotated while applying traction to avulse the few remaining strands of meniscus, and the fragment is removed from the joint (TECH FIG 2D).
- Occasionally, the meniscal fragment cannot be detached with the grasping forceps alone. With a grasper through the lateral portal for traction on the meniscus, an arthroscopic scissor can be passed through the same portal to complete the resection. If necessary, an accessory portal can be made for the scope so that the two anterior portals can be used for instruments.
- A motorized meniscal shaver is used to smooth the remaining rim.

### ARTHROSCOPIC PARTIAL MENISCECTOMY AND MENISCAL CYST DECOMPRESSION

- The meniscus is carefully probed to identify the extent of the meniscal tear. Radial tears are trimmed to a stable peripheral rim. For stable horizontal tears, only the inferior leaf is resected and the superior leaf is gently trimmed.
- The cyst is palpated externally, which may push the cyst material into the joint and decompress the cyst, allowing identification of the cyst communication.
- If this is not successful, a spinal needle can be inserted percutaneously through the cystic mass to help locate the track between the cyst and the meniscus. Punch forceps passed through the tear and tracked into the cyst may widen the track enough for the contents of the cyst to be evacuated into the joint.
- If necessary, a small, motorized shaver is inserted into the cyst to break up loculations, assist in cyst decompression, and stimulate inflammation and scarring of the cyst.

### ARTHROSCOPIC PARTIAL EXCISION OF DISCOID LATERAL MENISCUS

- The following principles can be applied to all three types of discoid lateral menisci, including incomplete, complete, and Wrisberg types.
- In young patients with small knees, a 2.7-mm arthroscope and small-joint instruments should be used.
- In older individuals, the standard 4-mm arthroscope is used. In addition to standard technique, anteromedial and lateral portals can be used for instrumentation while viewing through a medial midpatellar portal.
- With the knee in a figure 4 position, basket forceps are used to begin the central resection of the discoid tissue (TECH FIG 3A).
- With the discoid meniscus under direct observation, resection is planned so that a healthy peripheral meniscus about 8 mm wide remains.
- When the desired amount of meniscal tissue has been removed and the rim is balanced, the thickness of the inner edge is much greater than that after routine partial meniscectomy (TECH FIG 3B).
- For a Wrisberg-type discoid meniscus, a repair with saucerization is recommended; however, if an inadequate posterior tibial attachment is present, total meniscectomy may be indicated.

**TECH FIG 3 • A.** Knee is placed in figure 4 position for resection of discoid meniscus. B. Discoid meniscus with radial tear.
PEARLS AND PITFALLS

The number of portals should be minimized. ■ With multiple portals, the surgeon must watch for fluid extravasation.

The knife blade is directed medially or laterally away from the patellar tendon for horizontal portals and superiority away from the anterior of the menisci for vertical portals.

The leg holder or post is placed about 10 cm above the superior pole of the patella. ■ If too proximal or distal, the surgeon cannot obtain sufficient valgus stress to open the medial joint for inspection.

A systematic approach is used so that any pathology present can be identified.

1. The surgeon inspects the following:
   a. Anterior compartment (suprapatellar region, patellofemoral joint [including tracking], lower trochlea).
   b. Medial and lateral gutters
   c. Medial and lateral compartments
   d. Posterior compartment (by directing arthroscope medial to posterior cruciate ligament)

2. The surgeon probes the menisci superiorly and inferiorly: can have up to 5 mm physiologic excursion of posterior horn of medial meniscus; can have up to 10 mm physiologic excursion posterior horn of lateral meniscus.

3. The surgeon inspects for pathologic plicae that may mimic meniscal tear.

4. The surgeon inspects and probes for displaced meniscal fragments, which may be submeniscal or in the posterior compartment (FIG 9).

POSTOPERATIVE CARE

■ No brace or range-of-motion restrictions
■ Immediate full weight bearing with crutches as needed
■ Cold therapy
■ Nonsteroidal anti-inflammatories at 2 weeks if not contraindicated
■ Active, passive, and active-assisted range of motion immediately postoperatively
■ Straight-leg-raise exercises immediately
■ Return to sports when full range of motion is regained, no effusion is present, and strength is 80% of uninjured side (usually 4 to 6 weeks minimum)

OUTCOMES

■ The knee can function well without the meniscus, sometimes for the rest of a patient’s life, but late degenerative changes within the joint sometimes occur, and the loss of the meniscus undoubtedly plays some part in producing these changes.
■ In addition to the condition of the meniscus, numerous other factors can influence long-term function, such as joint alignment, laxity of the capsular or ligamentous structures, and incomplete rehabilitation of the musculature about the knee.

■ Fairbank10 described three changes he had observed in the knee, alone or in combination, in patients who had had a meniscectomy, at intervals ranging from 3 months to 14 years after the surgery:
   a. The development of an anteroposterior ridge that projected distally from the margin of the femoral condyle
   b. Flattening of the peripheral half of the articular surface of the condyle
   c. Narrowing of the joint space

   These changes have been reported in 40% to 90% of patients with meniscectomy in ACL-deficient knees.

Considerable evidence indicates that meniscectomy often is followed by degenerative changes within the joint, but whether the injury, the damaged meniscus itself, or its excision led to the degenerative changes cannot be determined with certainty in most of these studies. Probably all these factors, and others as well, have an influence.

■ Partial meniscectomy has been proven to have significantly better outcomes than total meniscectomy (90% and 68% good results, respectively, reported in comparison study).
- Generally, outcomes after medial partial meniscectomy (80% to 100% good to excellent results) have been better than after lateral partial meniscectomy (54% to 92% good to excellent results). A recent review of the literature, however, reported that there were consistently no significant differences in radiographic or functional outcome between medial and lateral meniscal injury in the studies included in their analysis.

- Reported results of partial meniscectomy for discoid meniscus in children are generally good (87% to 100% good to excellent results).

- Results tend to deteriorate with time because of degenerative changes in the knee joint; however, continued good to excellent results have been reported with follow-up as long as 20 years.

- Two primary factors associated with worse results of partial meniscectomy are preexisting osteoarthritis and ACL deficiency. Other factors suggested to predispose to poor outcomes are age more than 35 years, female gender, presence of medial cartilage degeneration, resection of the posterior third of the meniscus, and meniscal rim resection.

- Preoperative participation in sports has been shown to be a predictor of a better outcome.

COMPLICATIONS

- Possible complications after partial or total meniscectomy are the same as those after any arthroscopic procedure on the knee (see Chap. SM-31).

- Patients should be informed of the risks of infection, deep vein thrombosis (with or without pulmonary embolism), recurrent effusions, incomplete tear removal, synovial-cutaneous fistula, arteriovenous fistula, popliteal pseudoaneurysm, and compartment syndrome.

DEFINITION
- A meniscus tear results in mechanical disruption of the gross structure of the medial or lateral meniscus or both.
- The goals of meniscus repair are to preserve and optimize meniscus function and to restore joint biomechanics.

ANATOMY
- The medial meniscus and the lateral meniscus are crescent-shaped and triangular in cross section.
- The medial meniscus is C-shaped. It covers about 64% of the tibial plateau. Its width varies from anterior to posterior, with an average of 10 mm (FIG 1).
- The lateral meniscus is more circular. It covers about 84% of the tibial plateau, with an average width of 12 to 13 mm.
- The menisci are fibrocartilaginous structures made up of collagen (90% type I and the remainder made up of types II, III, V, and VI), fibrochondrocytes, and water.
- The collagen fibers are arranged in a circumferential pattern in the peripheral third, whereas the inner two thirds is organized with a combination of radial and circumferential fibers (see Fig 3A in Chap. SM-33).
- The menisci function to deepen the articular surface of the tibial plateau, providing shock absorption and compensating for gross incongruity between the articulating surfaces, acting as joint stabilizers. They provide joint lubrication and maintenance of synovial fluid and assist in providing nutrition of articular cartilage.16
- The vascular supply comes from the perimeniscal capillary plexus supplied by the medial and lateral inferior and superior geniculate arteries. The plexus penetrates the meniscus peripherally and its abundance decreases as it crosses centrally.
- This difference in vascularity creates the red-red, red-white, and white-white zones.2
- The meniscus contains free nerve endings and corpuscular mechanoreceptors, providing pain and proprioception in the knee joint.16

PATHOGENESIS
- Acute tears typically occur in younger patients from compression and rotational injury of the knee joint as it moves from a flexed to an extended position.
- Degenerative tears are typically chronic in nature, are found in older patients, are complex, and are usually irreparable.
- Medial meniscus tears most often occur in the stable knee or chronic anterior cruciate ligament (ACL)-deficient knee, whereas lateral tears occur more often in younger patients with acute ACL tears.
- Associated injuries are often found. The “terrible triad” consists of tears of the lateral meniscus, ACL, and medial collateral ligament. It is often sustained from a hyperextension with a valgus stress, such as during a “clipping” injury in football.
- Tears may be classified according to anatomic zone (as described by Cooper et al7), vascularity (red-red, red-white, white-white), or by tear pattern.
- Tear patterns are described as horizontal, radial, longitudinal, bucket-handle, oblique, or complex (see Fig 2 in Chap. SM-33).7

NATURAL HISTORY
- Walker and Erkman24 in 1975 found that with loads up to 150 kg, the lateral meniscus bore most of the weight bearing in that compartment, whereas the medial meniscus shared about 50% of the load with the articulating surfaces of the tibiofemoral joint.
- Partial and total meniscectomy has been shown to increase the contact stresses exerted on the articular cartilage, resulting in its degeneration and ultimately osteoarthritis.
- After partial meniscectomy, femoral–tibial contact areas decrease by about 10%, with peak local contact stresses (PLCS) increasing by about 65%. After total meniscectomy, contact areas decrease about 75% and PLCS increases about 235%.3
- PLCSs and contact areas were found to be the same with meniscus repair.3
- Partial meniscectomy has been shown to improve prognosis and decrease chondral wear compared to total meniscectomy.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history should include location of pain (joint line tenderness), recent traumas, prior injuries and surgery, as well as evidence of effusions, locking, catching, or instability (which may indicate associated ligamentous pathology).
- In addition, questions should be asked about the patient’s age, function, activity level, occupation, goals, expectations, and other pertinent medical problems. These will help the surgeon decide on nonsurgical versus surgical treatment and resection versus repair.
A complete examination of the knee should be performed, including evaluation for:
- Anterior and posterior ligament injury: Lachman, anterior and posterior drawer, pivot shift, along with a history of hearing a “pop” with injury and acute swelling
- Posterolateral corner injury: injury of the popliteus tendon, iliotibial band, popliteofibular ligament, biceps, and posterior capsule. Asymmetry on the dial (external rotation) test is the most sensitive examination.
- Medial and lateral collateral ligament injuries may be assessed by palpation and widening with varus–valgus stresses at 30 degrees and at full extension.

The examiner should also:
- Inspect for effusion. The presence of diffuse joint effusion is not specific enough. A localized swelling at the joint line may indicate a parameniscal cyst.
- Palpate all ligament and tendon insertions, as well as the patellofemoral joint; this may indicate associated pathology.
- Evaluate range of motion. Loss of extension or locking may relate to a displaced or bucket-handle tear. Pain with squatting may indicate a posterior horn tear.
- Perform the Apley test to look for a meniscus tear. Relief on distraction is found if a meniscus tear is the only pathology, but no relief will be found if a concomitant collateral ligament injury is present.
- Perform the Childress test, which is positive if the patient has pain or mechanical blocking; this may indicate a meniscus tear.

While assessing for the Merkel sign, pain with internal rotation of tibia is consistent with a medial meniscus tear; pain with external rotation is consistent with a lateral meniscus tear.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs should be taken to evaluate for bony pathology, extremity alignment, arthritis, chondrocalcinosis, or findings consistent with associated injuries such as a Segond sign (ACL injury), osteochondritis dissecans lesion, or osteochondral fracture.
  - Typically four views are obtained: a 30- or 45-degree posterioranterior flexion weight-bearing view, a true lateral view, a notch view, and a patella skyline view.
- Magnetic resonance imaging (MRI) is not always indicated to evaluate for meniscal pathology, but it is typically used and helpful in evaluation of associated injuries when a meniscus tear is suspected. The sensitivity of MRI for meniscus tears is reported as high as 96%, with a specificity of 97%.
- MRI classification is as follows:
  - Grade 1: small focal area of increased signal, not extending to the joint surface
  - Grade 2: linear area of increased signal, not extending to the joint surface
  - Grade 3: linear area of increased signal extending to the joint surface
- A linear abnormality is identified as extension to the articular surface on two consecutive images and is considered to have a high likelihood of being a true tear (FIG 2A).
- A bucket-handle tear may be identified by the “double PCL” (posterior cruciate ligament) sign (FIG 2B,C).

FIG 2 • A,B. Lateral and PA MRIs of meniscus tears. C. MRI of medial bucket-handle meniscus tear and double PCL sign. D,E. Sagittal and coronal MRIs of discoid lateral meniscus tears.
Evaluation of the meniscus postoperatively presents a challenge because the repair site becomes filled with fibrous scar and may continue to produce abnormal MR signal on postoperative imaging. Currently the best method of evaluation is with a gadolinium-enhanced MRI.

A discoid meniscus may be evident on MRI as a rectangular meniscus on all slices as opposed to the wedge shape typically seen. It is more commonly found in the lateral meniscus (FIG 2D,E).

DIFFERENTIAL DIAGNOSIS

- ACL or PCL tear
- Medial or lateral collateral ligament tear
- Osteochondritis dissecans lesion
- Patellofemoral syndrome
- Osteoarthritis
- Chondrocalcinosis

NONOPERATIVE MANAGEMENT

- Conservative treatment options include physical therapy, nonsteroidal anti-inflammatory medications, steroid injections, and activity modification.
- Typically, a stable longitudinal tear in the periphery less than 10 mm is likely to heal on its own.
- Bracing usually is not indicated in the treatment of meniscus tears.
- The expected result of nonoperative treatment is improved symptoms in 6 weeks, with return to full activities by 3 months.

SURGICAL MANAGEMENT

- Intervention may proceed after failure of conservative treatment or more urgently if the patient shows mechanical symptoms such as locking or catching. These may represent loose bodies or an unstable torn meniscus (ie, bucket-handle tear), which can cause significant articular damage if left untreated.
- With all meniscus pathology, the goal is to preserve as much meniscus as possible.
- Repair versus resection
  - The potential long-term benefit of repairing the meniscus is chondroprotection.
  - The surgeon should consider tear location, pattern, vascularity, and associated pathology when determining whether to repair or resect the meniscus.
  - The surgeon should consider the patient’s age, activity level, overall health, and compliance with a limited postoperative activity regimen.
  - When resection is performed, all efforts should be made to preserve as much viable meniscus as possible. Mobile, unstable meniscus fragments should be resected, leaving a smooth contour.
  - The meniscosynovial junction should be preserved because this is where the circumferential collagen fibers form the predominant amount of “hoop stresses.”
  - The surgeon should consider leaving a stable tear alone. An unstable tear will be easily mobilized, displaced at least 7 mm, and/or will have the ability to “roll” (FIG 3).

Preoperative Planning

- Before the surgery, all radiologic studies should be reviewed.
- The knee should be examined under anesthesia before beginning the surgery in an attempt to detect associated pathology.

The healing potential for a meniscus repair in conjunction with an anterior cruciate ligament reconstruction is far superior to that of a repair alone.

The surgeon should discuss with the patient the risks and benefits of the surgery as well as the principle of informed consent.

All patients should be apprised of the possibility of meniscus resection versus repair.

They should understand the implications of each in terms of short- and long-term consequences and postoperative rehabilitation protocols.

The surgeon may discuss the potential for associated pathology and may obtain a better understanding of the patient’s treatment preferences before entering the operating room.

This may be a particularly crucial conversation with an elite athlete who would prefer to undergo a resection in an attempt to return to competitive sport faster.

The anesthesia used is typically decided on by the anesthesiologist and orthopedist before entering the operating room. General anesthesia or a laryngeal mask airway (LMA) may be used.

We prefer to have the anesthesiologist provide sedation in conjunction with a local anesthetic administered by the surgeon.

We typically use a mixture of 0.5% bupivacaine and 1% lidocaine with epinephrine in equal proportions. About 30 to 40 cc is injected intra-articularly, and about 5 cc is injected into each portal site.

Positioning

- Typically the patient is lying supine.
- The two most popular methods of leg support are a knee holder (thigh immobilizer) and a lateral post.
- The knee holder should be placed perpendicular to the position of the femur at a level above the patella and portals that allows for a valgus force on the knee. The end of the table is dropped down below 90 degrees from horizontal to allow both legs to hang freely from the knees.
- The lateral post should be placed above the patella and angled outwardly to allow for a valgus force on the operative knee. This technique is performed without dropping the end of the table. The surgeon should check that the knee may be taken through a range of motion by abducting the leg against the lateral post with flexion of the knee off the side of the table.
• A tourniquet may be placed on the upper thigh if bleeding is suspected, such as in debridement of a hypertrophic fat pad.
• Padding of the contralateral leg is used to prevent pressure-related injury to the bony prominences or superficial nerves.

Approach
• The typical portal sites are a superomedial, anteromedial, and anterolateral portal (FIG 4).
  • The superomedial portal is typically made proximal to the superior pole of the patella in line with the medial border of the patella (medial to the quadriceps) and is directed in an oblique manner into the joint. This portal is typically used for outflow or inflow.
  • The anterolateral portal is created by making a small (about 6 mm) stab incision 1 cm proximal to the joint line and 1 cm lateral to the patella tendon. This area can be identified as the “soft spot.” This portal is used for insertion of the arthroscope.
  • The anteromedial portal is considered the working portal for insertion of instruments. It is typically made under direct visualization by inserting a spinal needle into the medial “soft spot” 1 cm medial to the patella tendon and 1 cm proximal to the joint line.
  • Accessory portals may include superolateral, posteromedial, posterolateral, midpatella, central, far medial, or lateral (Fig 4).
• The tears may be stimulated to heal with either rasping or trephination.
  • Rasping may be performed with either an arthroscopic shaver or a meniscal rasp that lightly abrades both the tibial and femoral edges of the tear site, as well as the meniscosynovial junction, to stimulate vascularity.
  • Trephination is performed by inserting a long 18-gauge needle either percutaneously or through the arthroscopic portals across the meniscus tear to create vascular channels. The surgeon should avoid perforation of the meniscus surface, causing further injury.

INSIDE-OUT TECHNIQUE
• This technique requires passage of double-loaded 2-0 or 0 nonabsorbable sutures with long flexible needles passed arthroscopically through thin cannulas (TECH FIG 1).
• It is best used for posterior horn, middle third, peripheral capsule, and bucket-handle tears.
• Before passage of the sutures, an incision is made posteromedial or posterolaterally to capture the needles as they exit through the capsule. In this manner, all neurovascular structures are protected.
• For passage of a needle through the medial compartment, the knee is placed in 20 to 30 degrees of flexion to avoid tethering the capsule.
  • A 4- to 6-cm posteromedial incision is made just posterior to the lateral collateral ligament, anterior to the biceps femoris tendon, extending one-third above and two-thirds below the joint line.
  • Dissection is continued anterior to the sartorius and semimembranosus musculature, deep to the medial head of the gastrocnemius.
  • The posterolateral incision is made with the knee in 90 degrees of flexion to allow the peroneal nerve, popliteus, and lateral inferior geniculate artery to fall posteriorly.
• A 4- to 6-cm incision is made just posterior to the lateral collateral ligament, anterior to the biceps femoris tendon, extending one-third above and two-thirds below the joint line.
• Dissection is continued between the iliotibial band and the biceps tendon and then proceeds deep and anterior to the lateral head of the gastrocnemius. On exposure of the capsule, a “spoon” or popliteal retractor is placed against the capsule to visualize the exiting needles.
• A single- or double-lumen cannula is passed through the arthroscopic portals to the site of the tear.
• Long flexible needles are then passed through the cannula, piercing the meniscus above and below the tear site and creating vertical mattress sutures.
• The needles are captured one at a time by an assistant who is retracting on the capsule. Care is taken not to pull either suture all the way through until both needles are passed.
• The sutures are then tensioned and tied to the capsule while viewing the repair arthroscopically.
OUTSIDE-IN TECHNIQUE

- This technique is performed by passing multiple long 18-gauge spinal needles percutaneously from outside of the knee to inside the knee joint (TECH FIG 2).
- This technique is best performed on tears of the anterior and middle third, as well as radial tears.
- Needles should be spaced about 3 to 5 mm apart.
- The needle should enter the joint through the periphery to achieve a vertical or horizontal mattress suture configuration.
- An absorbable monofilament suture is passed into the joint.
- A second needle with a wire retriever trocar is passed through the tear to retrieve the suture.
- After tensioning of the mattress suture, a 3- to 5-mm skin incision is made near the suture strands and blunt dissection carried down to the capsule with a hemostat.
- A probe may be used to retrieve the sutures and tie them down to the capsule under direct visualization, taking care to avoid incarceration of any neurovascular structures.

TECH FIG 1 • Inside-out repair technique. A. Diagram of technique. B. Skin incision on medial side. C. Skin incision on lateral side. D. Intraoperative image and popliteal retractor in place. E. The cannulas used to pass the needles.

ALL-INSIDE FIXATION TECHNIQUE

- Multiple proprietary fixation devices are available with variations on the popular reverse-barbed fishhook design (eg, Meniscus Arrow, Bionx, Blue Bell, PA; Biostinger, and ConMed Linvatec, Largo, FL; Dart, Arthrex, Naples, FL) (TECH FIG 3).
  - They are also referred to as first-generation fixators.
  - These devices are best used in vertical longitudinal tears in the red-white zone of the posterior horn.
  - They are typically made of bioabsorbable copolymers such as poly-L-lactic acid and poly-D-lactic acid.
- After identification of the tear site, accurate measurement of the size of the meniscus is performed with an arthroscopic measuring device.
- Insertion of the fixator must be performed perpendicular to the tear and parallel to the tibial surface.
- Fixators can be placed at 3- to 5-mm intervals.
- Care must be taken to implant the fixator so that it is seated flush or countersunk to the meniscus surface while spanning the tear equally on both sides to appropriately compress the tear.

TECH FIG 3 • Use of arthroscopic fixator. A. Meniscal fixators. B. Placement of meniscal arrow.
ALL-INSIDE SUTURE FIXATION TECHNIQUE

- Multiple proprietary designs are available (eg, FasT-Fix, Smith and Nephew, Andover, MA; RapidLoc, Mitek, Westwood, MA) (TECH FIG 4).
  - They are also referred to as second-generation fixators.
- The suture fixators are designed to allow repair of the meniscus with mattress sutures without creating an incision through the skin.
- The devices deploy two absorbable or nonabsorbable suture anchors with attached nonabsorbable sutures between them.
- The sutures can then be arthroscopically tied or they may come pretied, depending on proprietary design.
- After preparing the tear in the standard manner, the fixator should be inserted from the contralateral portal.
- Use of a curved needle provides the surgeon with more options compared to the straight needle with regard to position and reduction and insertion angles.
- Insertion of the needle through a sheath or insertion cannula prevents the delivery system from getting caught on loose tissue.
- The surgeon starts the repair from the center and works outward. This avoids gapping, ruffling, and dog-ears.
- The use of an outside-in stay suture may aid in holding the reduction until the mattress sutures can be placed.
- The devices are placed perpendicular to the tear.
- The first anchor should be placed superiorly and posteriorly and the second should be placed inferiorly and anteriorly across the tear to create a vertical mattress.
- The knot pusher is used to slide and manually assist in cinching down the knot; however, the surgeon should avoid overtightening and puckering the repair.
- The devices are placed about 4 to 5 mm apart.

REPAIR BIOLOGIC AUGMENTATION METHODS

- These techniques are indicated in cases of isolated meniscus repair (no concomitant ACL reconstruction) in which there is concern for healing.
- It is generally accepted that results of meniscus repair are improved when performed in conjunction with ACL reconstruction. The reason for the success is theoretically secondary to the release of intraosseous growth factors and cytokines when bone tunnels are drilled.
- Several methods have been used in an attempt to recreate that biologic advantage.
- Trephination or rasping may be performed in an attempt to increase vascularity delivered to the tear site.
- The use of fibrin clot or platelet-rich fibrin matrix attempts to deliver biologically active factors directly to the repair site.
- The fibrin clot technique introduces a concentrated autologous platelet-rich matrix to the repair site. The platelet-rich matrix technique is a refinement of the fibrin clot technique designed to deliver a more concentrated and volume-stable matrix to the repair site.
- The fibrin clot is performed by first obtaining 30 to 50 mL of blood from the patient intraoperatively and transferring it to a glass container. The blood is stirred with a sintered glass rod. A clot will form, which is blotted dry and then inserted using an arthroscopic grasper to the repair site. The clot is best placed with the fluid flow turned down and is best placed on the tibial site of the repair (TECH FIG 5A,B).
The platelet-rich fibrin matrix technique is performed by obtaining a smaller sample of autologous blood intraoperatively (about 10 mL) and placing it in a centrifuge for about 20 minutes. After centrifugation is completed, the fibrin matrix is retrieved and placed arthroscopically into the repair site in similar fashion to the fibrin clot. Proprietary technology is available (Cascade Autologous Platelet System, MTF, Edison, NJ) to perform this method (TECH FIG 5C,D).

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Repair of red-white and red-red tears only optimally.</td>
</tr>
<tr>
<td>• If concurrent pathology is present, meniscus tears should always be repaired in conjunction with anterior cruciate ligament reconstruction.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Tear site management</th>
</tr>
</thead>
<tbody>
<tr>
<td>• The tear should be approached from the contralateral portal.</td>
</tr>
<tr>
<td>• Preparation of the tear site with abrasion, débridement, or trephination is essential.</td>
</tr>
<tr>
<td>• The tear should be reduced accurately and reduction should be maintained during fixator placement.</td>
</tr>
<tr>
<td>• Tears should be bisected with reduction to avoid a dog-ear result.</td>
</tr>
<tr>
<td>• An anchoring stitch may assist with tear reduction.</td>
</tr>
<tr>
<td>• Hybrid techniques are very effective.</td>
</tr>
<tr>
<td>• Accessory portals improve access and fixation configuration.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Fixation placement</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Implants should be separated by about 5 mm.</td>
</tr>
<tr>
<td>• Implants should be placed perpendicular to the tibia.</td>
</tr>
<tr>
<td>• Implants should not be left proud.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Suture techniques</th>
</tr>

<tbody>
<tr>
<td>• Vertical mattress sutures are used when possible.</td>
</tr>
<tr>
<td>• Skin incisions are made in 90 degrees of flexion for posteromedial and posterolateral approaches.</td>
</tr>
<tr>
<td>• Sutures are passed in 20 degrees of flexion for medial tears and 90 degrees of flexion for lateral tears.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Rehabilitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Programs should be individualized for each patient in terms of protection, weight bearing, range of motion, and return to activities.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

• Postoperative care must be individualized based on tear geometry, repair construct strength, associated surgical procedures, and surgeon preference.
• In the operating room, our patients are placed in a knee immobilizer or hinged brace locked in extension.
• A patient with an isolated meniscus repair will remain partially weight bearing with crutches for about 1 month.
• Early range of motion is performed passively from postoperative day 1.
• Typically, range of motion is limited to 90 degrees for the first 3 weeks for nondisplaced meniscus tears and 4 to 6 weeks for displaced bucket-handle tears.
• Crutches are discontinued when the patient shows good quadriceps function and no antalgia.
Return to pivoting sports ranges from 4 to 6 months, or when the patient has no point tenderness or effusion and can show full extension and painless terminal flexion.

OUTCOMES

The success rate of meniscus repair has been estimated at 50% to 90%, with a higher likelihood of success when repair is performed in conjunction with an ACL reconstruction.

- Early studies by Cannon and Vittori reported on inside-out repairs of 90 knees. Overall clinical success was found to be 82%. Those repaired in conjunction with ACL reconstruction had a 93% success rate while isolated repairs were successful in only 50% of cases.
- Henning et al. reported on 260 repairs in 240 patients with follow-up of about 2 years. On arthroscopic second-look or arthrogram evaluation, inside-out repairs had a 62% success rate, with 17% incompletely healed and 21% not healed. Ninety-two percent of the knees were stable and ACL reconstruction was performed on 80% of them.
- Rodeo et al. found an overall success rate of 87% with use of the outside-in technique in 90 patients. He noted failure in 38% of the unstable knees, 15% in stable knees, and 5% in ACL-reconstructed knees.
- Studies have shown inside-out vertical mattress suture placement to be the strongest fixation technique, whereas the all-inside suture fixators provide excellent repair strength. The all-inside first-generation fixators have shown inferior results compared to the newer fixators.

Biomechanical testing of longitudinal tears in adult porcine meniscus showed mean load to failure of inside-out vertical mattress sutures to be 80.4 N, FasT-Fix 70.9 to 72.1 N (vertical and horizontal configuration), the Dart 61.7 N, horizontal sutures 55.9 N, Rapidloc 43.3 N, and Meniscus Screw (Arthrotek, Biomet, Warsaw, IN) 28.1 N.4

- Two recent studies showed early and intermediate success of Rapidloc.
  - One study found a 90.7% success rate with the use of Rapidloc to repair 54 menisci in 49 patients with an average follow-up of 34.8 months.15
  - Another prospective analysis of 32 meniscus repairs performed with Rapidloc, at an average of 32 months of follow-up, found clinical success in 87.5% of patients.2
  - A recent study of 61 menisci repaired with the FasT-Fix found, at an average follow-up of 18 months, a 90% success rate. ACL reconstruction was performed in 62% of them. Excellent or good clinical results were found on Lysholm knee scoring in 88%.10
- Spindler et al. compared 47 inside-out suture repairs to 98 all-inside meniscal arrow repairs, with clinical failure as defined as reoperation. They found seven failures in each group, but the mean time to follow-up was 68 months for the inside-out repairs and only 27 months for the all-inside group.
- One study of 60 meniscus repairs using the meniscal arrow showed a failure rate of 28% on MRI and repeat arthroscopy at a mean follow-up of 54 months. They found an increasing rate of significant complications in addition to meniscus repair failure, including chondral scoring, fixator breakage, and joint-line irritation.11
- Lee and Diduch also showed deteriorating results with first-generation fixators. They studied 32 meniscus repairs, all performed exclusively with arrows in conjunction with an ACL reconstruction. They reported a success rate of 90.6% at a mean follow-up of 2.3 years; subsequent reports of those same patients found a 71.4% success rate at a mean follow-up of 6.6 years.

COMPLICATIONS

- The overall incidence of complications from arthroscopic meniscus surgery is 0.56% to 8.2%.21
- Meniscus repair surgery has a higher complication rate than meniscus resection, with reports as high as 18%.20
- Commonly discussed complications include infection, deep vein thrombosis, vascular injury, and neurologic complications.
- The rate of infection is 0.23% to 0.42%, with an increasing incidence associated with extended operating time, extended tourniquet time, performance of multiple concurrent procedures, and a history of prior surgeries.1
- There is no clear consensus on the use of prophylactic perioperative antibiotics.
- There are published reports of an increased incidence of infection associated with intra-articular corticosteroid injections given intraoperatively.14
- When an infection has been diagnosed after a repair, it is appropriate to leave the implant or sutures in place; however, there is a higher failure rate associated with it.
- The incidence of deep vein thrombosis ranges from 1.2% to 4.9% after arthroscopic knee surgery.8 No clear consensus exists with regard to perioperative anticoagulation.
- The overall incidence of vascular complications is 0.54% to 1.0%, with complications including popliteal artery injury, pseudoaneurysm, and arteriovenous fistulas.9
- Neurologic complications include direct or indirect nerve injury or complex regional pain syndrome. The overall incidence is 0.06% to 2.0%.18
- Medial meniscus repairs using an inside-out or outside-in technique can result in saphenous neuropathy or neuropraxia, with reports of up to 43% of cases.23
- More recent reports of neuropraxia with all-inside techniques have yet to be published.
- The most common complications associated with the inside-out and outside-in techniques are traumatic neuropathy to the saphenous or peroneal nerves.
- The all-arthroscopic implant fixators can be associated with complications such as retained fragments that fail to resorb, broken implants, fixator migration, and inflammatory responses to the implant. A retained implant may cause further chondral damage secondary to implant abrasion.11

REFERENCES

DEFINITION
- An estimated 850,000 meniscal procedures are performed yearly in the United States.
- Although meniscus preservation is always preferable, large irreparable tears often require partial or subtotal meniscal excision.
- Many patients will become symptomatic in the meniscal-deficient compartment as the result of increased articular cartilage contact stresses and progressive cartilage deterioration.
- Meniscal allograft transplantation is an option in the carefully selected patient with symptomatic meniscal deficiency.

ANATOMY
- The menisci are semilunar fibrocartilaginous discs made of predominantly type I collagen. Water, which accounts for 70% of meniscal composition, is trapped within the matrix by negatively charged glycosaminoglycans (FIG 1).
- Only the peripheral third of the meniscus is vascularized (10% adjacent to popliteal hiatus). Blood is supplied via the perimeniscal capillary plexus with contributions from the superior and inferior medial and lateral geniculate arteries.
- Medial meniscus
  - The medial meniscus covers a smaller percentage of medial compartment surface than the lateral meniscus.
  - A portion of the anterior cruciate ligament (ACL) tibial insertion footprint lies between the anterior and posterior horn attachment sites.
- Lateral meniscus
  - The lateral meniscus covers a relatively larger percentage of the articular surface in its respective compartment than the medial meniscus.
  - The anterior horn attaches adjacent to the ACL and the posterior horn attachment is behind the intercondylar eminence.
  - The anterior and posterior horn attachments are closer to each other than the medial meniscus without a ligament insertion footprint interposed between the two sites. This makes the lateral meniscus more amenable to a bone bridge transplantation technique.
  - A discoid variant is found in 3.5% to 5% of patients.

PATHOGENESIS
- Meniscal pathology is generally of two types:
  - Acute traumatic tears
    - These injuries typically occur in a previously relatively “healthy” meniscus in patients younger than 35.
    - They may also occur in older individuals, but typically in the setting of an acute ACL tear.
    - Traumatic tears often include unstable longitudinal tears in the vascular zone, which are optimal candidates for meniscal repair.
    - They often occur in association with combined knee injuries (ACL, medial collateral ligament).
  - Degenerative tears
    - This is a more complex tear pattern that typically occurs in patients older than 35.
    - Often a relatively minor trauma or event “breaks the camel’s back” and a tear propagates through degenerative meniscal tissue.
    - These are not repairable.
  - Risk factors for meniscal tears include sports participation (especially jumping and cutting sports at risk for concurrent ACL injury), age, higher body mass index, occupational kneeling and squatting (associated with degenerative rather than acute traumatic meniscal lesions), level of activity, and ACL instability.
  - The association of meniscal tears with ACL tears is well documented. Lateral meniscal injuries occur more frequently with acute ACL disruption, while medial meniscal injuries occur more often in the setting of chronic ACL insufficiency.
  - Irreparable tear patterns or failed previous meniscal repairs often necessitate arthroscopic meniscal excision of the tear component. The degree of tear propagation typically dictates the resection required.

NATURAL HISTORY
- Meniscectomy can decrease contact area by 75% and increase joint contact stresses by over 200%.1
- Contact stresses increase as a function of the amount of meniscus resected.
- These increases in joint contact stress often lead to premature cartilage deterioration and the development of osteoarthritis. Although patients often remain relatively asymptomatic until they have advanced degenerative changes, many patients (who tend to be younger and more active) develop pain earlier in the degenerative process.
- Lateral meniscectomy is considered to have a poorer prognosis than medial meniscectomy.
- The medial meniscus is the secondary stabilizer to anterior tibial translation. Medial meniscectomy (posterior horn) in the ACL-deficient knee often increases tibial translation and instability.

Meniscus implantation decreases peak stresses and improves contact mechanics but does not restore perfect knee mechanics.\textsuperscript{5,9}

PATIENT HISTORY AND PHYSICAL FINDINGS

Potential transplant patients are typically younger than 40 years of age, with an absent or nonfunctioning meniscus, who are symptomatic from their meniscal insufficiency. The upper limit is generally age 50 (not absolute) for highly active patients who are not good candidates for arthroplasty.

- A detailed history includes specific symptoms, prior injuries, and subsequent surgery. Arthroscopy pictures are helpful in determining the degree of meniscal resection and the condition of the articular cartilage.
- Symptomatic postmeniscectomy patients typically present with joint line pain (sometimes subtle), swelling, and pain associated with barometric pressure changes. Symptoms are usually activity-related.
- The physical examination should focus on determining pain location, ligament stability, and alignment, assessing the cartilage, and ruling out elements of the differential diagnosis.
- Palpating the joint line for tenderness will localize the source of pain.
- Sharp pain on the McMurray test may indicate recurrent meniscal injury or chondral lesion versus meniscal insufficiency (dull ache).
- The Lachman test assesses for concomitant ACL pathology, which should be addressed at the time of surgery.
- Concerns about malalignment and gait problems necessitate long-leg alignment films.
- Symmetric range of motion is needed before the transplant.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs
  - Anteroposterior (AP) view of both knees in full extension (FIG 2A): Look for subtle joint space narrowing.

Meniscal Allograft Sizing Methods

<table>
<thead>
<tr>
<th>Sizing Method</th>
<th>Strengths and Weaknesses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Direct measurement</td>
<td>Contralateral knee may be used for sizing, though some variability exists in menisci of opposite knees.</td>
</tr>
<tr>
<td>Plain radiographs</td>
<td>The consistent relationship between meniscal size and landmarks in plain radiographs is often used by tissue banks for allograft sizing. By using measurements of the length and width of the medial and lateral tibial plateaus, McDermott et al determined that meniscal size can be predicted with a mean error rate of 5%. Although compared to plain radiographs MRI is historically considered to be slightly more accurate at sizing allografts, Shaffer et al found that only 35% of menisci measured with MRI were found to be within 2 mm of the actual size needed. Carpenter et al reported that MRI consistently underestimated the anteroposterior and mediolateral sizes of both the medial and lateral meniscus but was more accurate in estimating meniscal height. They concluded that CT and plain radiographs were more useful in allograft sizing.</td>
</tr>
<tr>
<td>MRI</td>
<td></td>
</tr>
<tr>
<td>CT</td>
<td></td>
</tr>
</tbody>
</table>

- Weight-bearing 45-degree flexion posteroanterior view: Look for subtle joint space narrowing.
- Merchant view
- Non-weight-bearing lateral views
- Long-leg alignment films (if malalignment is suspected)
- MRI: to assess menisci, articular cartilage, and subchondral bone (FIG 2B).
- Bone scan can be considered and may reveal increased activity in the involved compartment. However, it is not typically used and its sensitivity in this setting is unknown.
- Diagnostic arthroscopy is often recommended.
  - It will accurately define the extent of meniscectomy and the degree of arthrosis if previous arthroscopic images are unavailable or unclear, or if more than 1 year has elapsed since the last arthroscopy (FIG 2C).
- Outerbridge grade III or less articular cartilage damage is acceptable (grade I or II is preferable) unless a focal grade IV lesion is addressed concurrently with a cartilage resurfacing procedure.

**DIFFERENTIAL DIAGNOSIS**

- Recurrent meniscal tear
- Chondral or osteochondral lesion (may be the primary cause of pain but may require chondroprotection of meniscus transplant)
- Advanced bipolar degenerative arthritis
- Synovitis
- Patellofemoral pain (radiating medial)
- Extra-articular sources (ie, hamstring or pes tendinitis)

**NONOPERATIVE MANAGEMENT**

- Activity modification (nonimpact activities and exercises)
- Appropriate pharmacologic therapy
- Injection therapy (may be helpful for diagnostic purposes as well)
- Unloader braces
- A potential exception to nonsurgical management may be in the setting of the chronically ACL-insufficient knee or failed ACL-reconstructed knee with medial meniscal deficiency.
- A concomitant reconstruction of the ACL with meniscal allograft replacement may improve joint stability, ACL graft survival, and eventual clinical outcome.
- This is a new relative indication.

**SURGICAL MANAGEMENT**

- Indications are patient younger than 40 years with an absent or nonfunctioning meniscus and with pain due to meniscal insufficiency or progressive joint space narrowing.
- Upper limit is generally age 50 for highly active patients who are not good candidates for arthroplasty.
- Contraindications to surgery include immunodeficiency, inflammatory arthritis, prior deep knee injection, osteophytes indicating bony architectural changes, marked obesity, Outerbridge grade IV articular changes (focal chondral defects can be addressed concurrently), knee instability, or marked malalignment (unless these issues are corrected).

**Preoperative Planning**

- Graft sizing: Although size matching of meniscal allografts to recipient knees is thought to be critical, the tolerance of size mismatch is unknown. While various sizing methods have been proposed, measurements based on plain radiographs and MRI are most commonly used (Table 1).
- Meniscal allografts are procured under strict aseptic conditions within 12 hours of cold ischemic time in accordance with standards established by the American Association of Tissue Banks for donor suitability and testing (Table 2).
■ All equipment should be ordered and readily available (ie, commercially available meniscal workstations).
■ An experienced assistant is very valuable for this procedure.

### Positioning
■ The patient is placed in the supine position with the knee at the table break (FIG 3).
■ For a lateral meniscal transplant, there is the option of a figure 4 position versus the leg over the table break for femoral distractor application (see Approach).

### Approach
■ For the lateral meniscus, a lateral parapatellar arthrotomy with posterolateral meniscus repair approach is used.
■ For the medial meniscus, a medial parapatellar arthrotomy with posteromedial meniscus repair approach is used.

![FIG 3 • Patient positioned with the knee at the table break. Femoral distractor optimizes compartment distraction with the knee flexed.](image)

### LATERAL MENISCUS GRAFT PREPARATION
■ A previously size-matched lateral meniscus with the attached tibial plateau is thawed in a saline and antibiotic solution.
■ Remove soft tissue from the meniscus (capsular tissue) (TECH FIG 1A).
■ Always use the bone bridge-in-slot technique; it maintains the bridge of bone between the anterior and posterior insertion sites.
■ Commercially available meniscus workstations can facilitate bone bridge preparation into various shapes that will match tibial recipient sites (Arthrex, Naples, FL) (TECH FIG 1B,C).
■ The most common bone preparation techniques include keyhole, dovetail, and slot configurations (TECH FIG 1D).
■ Prepare the bone bridge shape between the meniscus insertion sites using the appropriate workstation (TECH FIG 1E).
■ During bone preparation, be careful not to injure the meniscus insertion sites.
■ Mark the superior surface of the meniscus and the popliteal hiatus with a surgical marker.
■ Using 10-inch flexible meniscus repair needles (Ethibond, Somerville, NJ), place one or two vertical mattress sutures (may place up to four if desired) through the posterior horn of the meniscus (TECH FIG 1F,G). Do not cut off the needles. These will serve as passage sutures and are used for fixation as well.

![TECH FIG 1 • Lateral meniscus graft preparation. A. Prepreparation lateral meniscus graft (after capsular soft tissue has been removed). B. Preparing a keyhole graft with the workstation. C. Dovetail workstation. (continued)](image)
LATERAL MENISCUS APPROACH AND TIBIAL PREPARATION

- A combined arthroscopic and lateral parapatellar arthrotomy approach is performed.
- Perform an arthroscopic débridement and excoriation to the far peripheral meniscal rim or joint capsule with a shaver or meniscal rasp.
- A no. 15 blade may be used to excise the anterior horn and any remnant of the body.
- Use an arthroscopic burr to create a small trough in line with the anterior and posterior horn attachments (guide for recipient site) (TECH FIG 2A).
- Expose the proximal tibia through a small lateral parapatellar arthrotomy in line with the trough (TECH FIG 2B).
- Commercially available instrumentation will facilitate creation of the tibial recipient site in line with the anterior and posterior horn attachments (Arthrex, Naples, FL) (TECH FIG 2C–E).
- Take care to avoid penetration through the posterior cortex.
- Perform posterolateral exposure to receive inside-out sutures (meniscus repair approach) (TECH FIG 2F).
DELIVERY AND FIXATION OF LATERAL MENISCUS

- Before delivery of the graft into the recipient site, place the 10-inch needles from the passage sutures through the miniarthrotomy and posterolateral capsule to assist in delivery of the graft (TECH FIG 3A).
- Exposure, retraction, and needle retrieval are identical to an inside-out repair technique.
- Plan optimal placement of sutures through the capsule relative to their position in the meniscus (TECH FIG 3B). Use the popliteus tendon and the popliteal hiatus in the graft as a guide for suture placement.
- By simultaneously inserting the shape-matched donor graft into the tibial recipient site and pulling on the posterior inside-out passage suture, the graft is delivered to re-establish the normal insertion site (TECH FIG 3C).
- A varus stress to the knee, combined with pulling on the posterior passage sutures, will help reduce the posterior horn under the femoral condyle (TECH FIG 3D).
- Matching the anterior cortices (graft and recipient) and bringing the knee through a range of motion will assist in final anteroposterior positioning.
- Place additional inside-out meniscus sutures with the suture cannula placed in the medial portal. The scope is placed into the miniarthrotomy.

Tech Fig 2 (continued) D. Preparation of dovetail recipient site. E. Completed keyhole recipient site. F. Posterolateral exposure.

Tech Fig 3 Delivery of lateral meniscus. A. Ten-inch needles from the passage suture are placed through the posterolateral capsule and retrieved by the assistant. B. Inside-out vertical sutures are placed through the appropriate location within the posterolateral capsule. (continued)
TECH FIG 3 • (continued) C,D. The dovetail graft is delivered into the recipient site. E. Posterior horn is reduced by pulling on the posterior passage suture combined with varus stress to the knee. F. Completed lateral meniscus transplant.

- Additional anterior sutures can be placed through the anterior arthrotomy using standard open suturing techniques.
- Tie sutures with the knee in flexion (TECH FIG 3E,F).
- An interference screw or transosseous suture fixation may be placed with the slot technique, but this is typically unnecessary with the dovetail and keyhole technique.

MEDIAL MENISCUS GRAFT PREPARATION

- A previously size-matched medial meniscus with the attached tibial plateau is thawed in a saline and antibiotic solution. Remove soft tissue as described for the lateral meniscus.
- Medial meniscal allografts may be fashioned with or without bone plugs at the anterior and posterior horn insertion sites (TECH FIG 4A,B).
- For preparation without bone plugs, detach the anterior and posterior horns from the bone block and whipstitch each horn with heavy nonabsorbable suture. We do not typically use this technique unless a plug fractures.
- For preparation with bone plugs (recommended), place a 2.4-mm Beath guide pin through the bone block into the posterior insertion site at about a 60-degree angle. Place
MEDIAL MENISCUS APPROACH AND TIBIAL PREPARATION

- The case is performed via arthroscopic, medial parapatellar, and posteromedial meniscal repair approaches (TECH FIG 5A).
- The remaining meniscus is débrided, leaving 1 mm of meniscal rim. The surrounding capsule and meniscal bed is abraded with the shaver and rasps.
- To visualize and access the posterior horn insertion site, perform a small notchplasty of the medial wall of the notch inferior to the posterior cruciate ligament (PCL) insertion. Likewise, débride back the medial tibial spine until easy access is obtained (TECH FIG 5B).
- Place a vertical passing stitch of nonabsorbable suture up the guide pin hole, through the meniscal tissue, then back down the guide pin hole for each bone plug.
- Perform a medial parapatellar incision, extending distally to allow access to the anteromedial proximal tibia. Do not perform the arthrotomy portion until the posterior tunnel is complete.
- Repeat these steps for the anterior horn insertion, but angle the guide pin approximately 20 degrees and create a bone plug 10 mm in diameter. Place a heavy nonabsorbable suture (no. 2 FiberWire) up the guide pin hole, through the meniscal tissue, then back down the guide pin hole for each bone plug.

a commercially available collared pin into the 2.4-mm hole. Ream over the collared pin using an 7- or 8-mm coring reamer (creates a plug 6 or 7 mm in diameter) (TECH FIG 4C). Trim and taper the end to create a 10-mm-long plug.

- Repeat these steps for the anterior horn insertion, but angle the guide pin approximately 20 degrees and create a bone plug 10 mm in diameter. Place a heavy nonabsorbable suture (no. 2 FiberWire) up the guide pin hole, through the meniscal tissue, then back down the guide pin hole for each bone plug.

- Place a vertical passing stitch of nonabsorbable suture at the junction of the posterior and middle thirds of the meniscus.
- Mark the anterior and posterior horns on the superior meniscal surface.
Under direct visualization, position a variable-angle ACL-PCL tibial drill guide such that the guide pin will exit in the center of the native posterior horn insertion site footprint (TECH FIG 5C,D).

Drill a 9-mm tibial tunnel. Débride and chamfer the intra-articular portion of the tunnel. Pass a shuttle suture up the tunnel and out the medial portal (TECH FIG 5E).

Complete the medial parapatellar arthrotomy, incorporating the medial portal (do not cut the shuttle suture) (TECH FIG 5F).

Perform posteromedial exposure to receive inside-out sutures (meniscus repair approach).

**DELIVERY AND FIXATION OF MEDIAL MENISCUS**

Shuttle-exchange the shuttle sutures with the posterior bone plug suture and allograft passing suture. Via the parapatellar arthrotomy, deliver the meniscal allograft into the knee and fully seat the posterior bone plug into the posterior tunnel (TECH FIG 6A,B). Apply a valgus stress to the knee while pulling on the posterior bone plug sutures and the posterior passing sutures.

Using zone-specific cannulas (Linvatec, Largo, FL), suture the allograft to the periphery approximately two thirds of the way posterior to anterior with multiple vertical mattress sutures.

Through the parapatellar arthrotomy, determine the anterior horn insertion site and place a Beath guide pin in its center.

Drill a blind 10-mm tunnel vertically to a depth sufficient to accept the anterior allograft bone plug (TECH FIG 6C).

Drill a 2-mm hole perpendicular to the tunnel from the anterior tibial cortex entering the tunnel base.

**TECH FIG 6 • A,B.** Meniscus delivery. Shuttle suture and delivery of the posterior bone plug and meniscus. C. Anterior recipient tunnel created by reaming over guide pin. D. Anterior bone plug seated into tunnel. E. Bone plug sutures tied over anterior bone bridge. *(continued)*
POSTOPERATIVE CARE
- Postoperative rehabilitation may need to be altered based on concomitant procedures.
- A hinged knee brace locked in extension is used for 6 weeks.
- Weight bearing as tolerated is typically permitted with the knee braced in full extension (this may be limited by other procedures).
- Range of motion is limited between 0 and 90 degrees for the first 6 weeks. Flexion is increased between 6 and 12 weeks.
- Closed-chain exercises, cycling, and swimming are started at 6 weeks.
- Running may begin at 4 to 6 months.
- Squatting and pivoting sports are not allowed for 6 to 9 months.

OUTCOMES
- With appropriate indications, current success rates for allograft meniscus transplantation are about 75% to 85%. 3,4,6,10
- Bone plug fixation may improve outcomes, although this is controversial.
- Poor results are typically associated with more advanced articular cartilage degeneration.
Meniscus transplants that are combined with articular cartilage resurfacing or realignment procedures can yield favorable outcomes.

One study reported that 86% of patients with a combined ACL reconstruction and meniscus transplant had normal or near-normal International Knee Documentation Committee (IKDC) scores, with an average maximum KT arthrometer side-to-side difference of 1.5 mm.¹²

**COMPLICATIONS**

- Nonhealing or incomplete healing
- Infection
- Neurovascular injury
- Loss of motion
- Meniscus tear or extrusion (late)
- Persistent or progressive symptoms (typically related to articular cartilage)

**REFERENCES**

DEFINITION
- Chondral defects in the knee are common.
- The lesions may be partial- or full-thickness (FIG 1), through all layers of the articular cartilage down to the level of the subchondral bone.
- Chondral defects may be acute or chronic.
- These articular cartilage lesions may present in a variety of clinical settings and at different ages.5–10

ANATOMY
- The articular cartilage of the knee is 2 to 4 mm thick, depending on the location within the joint.
- The articular cartilage is avascular tissue that is devoid of nerves and lymphatics.
- Relatively few cells (chondrocytes) are present in the abundant extracellular matrix.
- These factors are critical in the lack of a spontaneous or naturally occurring repair response after injury to articular cartilage.

PATHOGENESIS
- The shearing forces of the femur on the tibia as a single event may result in trauma to the articular cartilage (FIG 2), causing the cartilage to fracture, lacerate, and separate from the underlying subchondral bone or separate with a piece of the subchondral bone.
- Chronic repetitive loading in excess of normal physiologic levels also may result in fatigue and failure of the chondral surface.
- Single events usually occur in younger patients, whereas chronic degenerative lesions are seen more commonly in persons of middle age and older.5–10
- Repetitive impacts can cause cartilage swelling, an increase in collagen fiber diameter, and an alteration in the relation between collagen and proteoglycans.

NATURAL HISTORY
- Articular cartilage defects that extend for the full thickness to subchondral bone rarely heal without intervention.5–10
- Some patients may not develop clinically significant problems from acute full-thickness chondral defects, but most eventually suffer from degenerative changes that can be debilitating.

FIG 1 • A. A full-thickness chondral defect through all layers of the articular cartilage is outlined (arrows). B. A full-thickness chondral lesion.

FIG 2 • A shearing injury has resulted in a full-thickness chondral defect, as seen on this MRI scan. The dark arrow denotes the cartilage defect, and the light arrows show the limits of the subchondral bone edema secondary to the shearing injury. (Courtesy of Dr. Charles Ho, Vail, CO.)
Acute events may not result in full-thickness cartilage loss but, rather, may start a degenerative cascade that can lead to chronic full-thickness loss.

The degenerative cascade typically includes early softening and fibrillation (grade I); fissures and cracks in the surface of the cartilage (grade II); severe fissures and cracks with a “crab meat” appearance (grade III); and, finally, exposure of the subchondral bone (grade IV).

PATIENT HISTORY AND PHYSICAL FINDINGS

The physical diagnosis can be difficult to establish, especially if the chondral defect is isolated.

Chondral lesions can be located on the joint surfaces of the femur, tibia, or patella.

Point tenderness over a femoral condyle or tibial plateau is a useful finding, but is not diagnostic.

If compression of the patella elicits pain, a patellar or trochlear lesion may be indicated.

Joint effusion may be present, but it is not a consistent finding.

Catching or clicking may be present, especially if there is an elevated flap of cartilage.

Restricted range of motion (ROM) can be associated with many pathologic conditions of the knee, but the ROM should be documented as a baseline prior to any treatment.

Physical examinations should be performed, as follows:

- The patella is palpated in superior-inferior and medial-lateral directions for evidence of effusion. About 50% of patients with chondral defects have an effusion.
- The Lachman test is used to rule out ligamentous instability by applying anterior force to the tibia with the knee in 20 to 30 degrees of flexion.
- The thumb and index finger are used to place digital pressure over all geographic areas of the knee to detect point tenderness; this finding is useful but is not in itself diagnostic.
- A palpable or audible pop in combination with pain is considered a positive result to the McMurray’s test, indicating a meniscus lesion rather than a chondral lesion.

IMAGING AND OTHER DIAGNOSTIC STUDIES

For diagnostic imaging, angular deformity and joint space narrowing are assessed using long standing radiographs.

Two methods for radiographic measurement of the biomechanical alignment of the weight-bearing axis of the knee are used in our facility:

- The angle between the femur and tibia on anteroposterior (AP) views obtained with the patient standing.
- The weight-bearing mechanical axis drawn from the center of the femoral head to the center of the tibiotarsal joint on long (~51 inches/130 cm) standing radiographs (FIG 3A).

If the angle drawn between the tibia and femur shows more than 5 degrees of varus or valgus compared with the normal knee, this amount of axial malalignment would be a relative contraindication for microfracture.

We rely most often on the mechanical axis. It is preferable for the mechanical axis weight-bearing line to be in the central quarter of the tibial plateau of either the medial or lateral compartment.

If the mechanical axis weight-bearing line falls outside the quarter of the plateaus closest to the center (FIG 3B), either medial or lateral, this weight-bearing shift also would be a relative contraindication if left uncorrected. In such cases, a realignment procedure should be included as a part of the overall treatment regimen.
Standard AP, lateral, and weight-bearing radiographic views with knees flexed to 30 to 45 degrees also are obtained. MRI that uses newer diagnostic sequences specific for articular cartilage is crucial to our diagnostic workup of patients with suspected chondral lesions (FIG 3C).

DIFFERENTIAL DIAGNOSIS
- Meniscus tear
- Loose bodies
- Attached chondral flap
- Symptomatic plica
- Synovitis
- Chondral bruising, with or without subchondral edema

NONOPERATIVE MANAGEMENT
- Patients with acute chondral injuries are treated as soon as practical after the diagnosis is made, especially if the knee is being treated concurrently for meniscus or anterior cruciate ligament pathology.
- Patients with chronic or degenerative chondral lesions often are treated nonoperatively (conservatively) for at least 12 weeks after a suspected chondral lesion is diagnosed clinically.
- This treatment regimen includes activity modification, physical therapy, nonsteroidal anti-inflammatory drugs, viscosupplement injections, and possibly dietary supplements that may have cartilage-stimulating properties.
- If nonoperative treatment is not successful, then surgical treatment is considered.

SURGICAL MANAGEMENT
- Microfracture initially was designed for patients with post-traumatic articular cartilage lesions of the knee that had progressed to full-thickness chondral defects.
- The microfracture technique still is most commonly indicated for full-thickness loss of articular cartilage in either a weight-bearing area between the femur and tibia or an area of contact between the patella and the trochlear groove.
- Unstable cartilage that overlies the subchondral bone also is an indication for microfracture (FIG 4).
- If a partial-thickness lesion is probed and the cartilage simply scrapes off down to bone, we consider this a full-thickness lesion.

Degenerative joint disease in a knee that has proper axial alignment is another common indication for microfracture.
- These lesions all involve loss of articular cartilage at the bone–cartilage interface.

Preoperative Planning
- All imaging studies are reviewed.
- MRI scans are re-reviewed for presence of concomitant pathology.
- Radiographs are carefully studied for fractures, loose bodies, axial alignment, and joint space narrowing.
- The surgical plan should include addressing concomitant pathology concurrently, as appropriate.
- Examination under anesthesia should be accomplished before skin preparation and draping.

Positioning
- The patient is positioned supine.
- Initially, for the diagnostic portion of the arthroscopy, the foot is on the table.
- For the definitive procedure, the distal portion of the table is lowered so that the foot is off the table and the knee is flexed 90 degrees (FIG 5).
- A lateral post is raised so that a varus force can be placed on the joint to increase visualization as necessary.

Approach
- Our primary approach to chondral lesions is arthroscopic microfracture chondroplasty (Table 1).

FIG 4 • The probe (red arrow) shows that this chondral defect has areas of unstable cartilage (black arrows) that are fissured fully to subchondral bone. These unstable cartilage segments must be removed until a stable margin is achieved.

FIG 5 • For the definitive procedure, the distal portion of the table is lowered so that the foot is off the table and the knee is flexed 90 degrees.
DIAGNOSTIC ARTHROSCOPY

- Three portals routinely are made about the knee for use of the inflow cannula, the arthroscope, and the working instruments (TECH FIG 1).
- Typically, a tourniquet is not used during the microfracture procedure; rather, the arthroscopic fluid pump pressure is varied to control bleeding.
- An initial, thorough diagnostic examination of the knee should be done.
- All geographic areas of the knee must be inspected carefully, including the suprapatellar pouch, the medial and lateral gutters, the patellofemoral joint, the intercondylar notch and its contents, and the medial and lateral compartments, including the posterior horns of both menisci.
- All other intra-articular procedures are done before microfracture.
  ▪ This technique helps prevent loss of visualization when fat droplets and blood enter the knee from the microfracture holes.
  ▪ Importantly, particular attention must be paid to soft tissues such as plicae and the lateral retinaculum that potentially could produce increased compression between cartilage surfaces.

INITIAL PREPARATION

- After careful assessment of the full-thickness articular cartilage lesion, the exposed bone is débrided of all remaining unstable cartilage.
- A hand-held curved curette (TECH FIG 2A) and a full radius resector (TECH FIG 2B) are used to débride the cartilage.
  ▪ It is critical to débride all loose or marginally attached cartilage from the surrounding rim of the lesion.
  ▪ The calcified cartilage layer that remains as a cap to many lesions must be removed, preferably with a curette (TECH FIG 2C).
- Thorough and complete removal of the calcified cartilage layer is extremely important, based on animal studies we have completed.\(^2\)
- Care should be taken to maintain the integrity of the subchondral plate by not débriding too deeply.
- This prepared lesion, with a stable perpendicular edge of healthy, well-attached viable cartilage surrounding the defect (TECH FIG 2D), provides a pool that helps hold the marrow clot—“super clot”—as it forms.
After preparation of the lesion, an arthroscopic awl is used to make multiple holes, or “microfractures,” in the exposed subchondral bone plate.

An awl with an angle that permits the tip to be perpendicular to the bone as it is advanced, typically 30 or 45 degrees, is used.

A 90-degree awl is available that should be used only on the patella or other soft bone. The 90-degree awl should be advanced only manually, not with a mallet.

The holes are made as close together as possible but not so close that one breaks into another, thus damaging the subchondral plate between them.

This technique usually results in microfracture holes that are approximately 3 to 4 mm apart.

When fat droplets can be seen coming from the marrow cavity, the appropriate depth (approximately 2–4 mm) has been reached.

Arthroscopic awls produce essentially no thermal necrosis of the bone compared with hand-driven or motorized drills.

Microfracture holes around the periphery of the defect should be made first, immediately adjacent to the healthy stable cartilage rim (TECH FIG 3A,B).

The process is completed by making the microfracture holes toward the center of the defect (TECH FIG 3C).

The treated lesion is assessed at the conclusion of the microfracture to ensure a sufficient number of holes have been made before reducing the arthroscopic irrigation fluid flow.

After the arthroscopic irrigation fluid pump pressure is reduced, the release of marrow fat droplets and blood from the microfracture holes into the subchondral bone is observed under direct visualization (TECH FIG 4).

The quantity of marrow contents flowing into the joint is judged to be adequate when marrow is observed emanating from all microfracture holes.

Finally, all instruments are removed from the knee and the joint is cleared of fluid.
POSTOPERATIVE CARE

- We prescribe cold therapy for all patients postoperatively, and it is continued for 1 to 7 days.5–10
- The specific post-microfracture rehabilitation protocol recommended depends on both the anatomic location and the size of the defect.3,4
- If other intra-articular procedures are done concurrently with microfracture, such as anterior cruciate ligament reconstruction, we do not hesitate to alter the rehabilitation program as necessary.3
- After microfracture of lesions on the weight-bearing surfaces of the femoral condyles or tibial plateaus, we initiate immediate motion with a continuous passive motion (CPM) machine in the recovery room.5–10
- The initial ROM typically is 30 to 70 degrees, which is increased as tolerated in 10- to 20-degree increments until full passive ROM is achieved.
- The machine usually is set at 1 cycle per minute, but the rate can be varied based on patient preference and comfort.
- The goal is to have the patient in the CPM machine for 6 to 8 hours every 24 hours.
- If the patient is unable to use the CPM machine, instructions are given for passive flexion and extension of the knee with 500 repetitions three times per day and encouragement to gain full passive ROM of the injured knee as soon as possible after surgery.
- Crutch-assisted touchdown weight-bearing ambulation (10% of body weight) is prescribed for 6 to 8 weeks, depending on the size of the lesion.
- Patients with lesions on the femoral condyles or tibial plateaus rarely use a brace during the initial postoperative period.
- Patients begin therapy immediately after surgery with an emphasis on patellar mobility and ROM, with instructions to perform medial to lateral and superior to inferior movement.

TECH FIG 5 • Chronic degenerative chondral lesions commonly have extensive eburnated bone and bony sclerosis with thickening of the subchondral plate, making it difficult to do an adequate microfracture procedure. The black arrow points to a single microfracture hole that has been made to help assess the depth of eburnated or sclerotic bone that must be removed before performing the microfracture procedure.
of the patella as well as medial to lateral movement of the quadriceps and patellar tendons (FIG 6).

- This mobilization is crucial in preventing patellar tendon adhesions and associated increases in patellofemoral joint reaction forces.
- ROM exercises (without ROM limitations), quadriceps sets, straight leg raises, hamstring stretching, and ankle pumps also are initiated the day of surgery.
- Stationary biking without resistance and a deep water exercise program are initiated at 1 to 2 weeks postoperatively.
- After 8 weeks of touchdown weight bearing, the patient is progressed to weight bearing as tolerated, typically weaning off crutches within 1 week.
- Restoration of normal muscular function through the use of low-impact exercises is emphasized during weeks 9 through 16.
- Depending on the clinical examination, the patient’s size, the sport, and the size of the lesion, we usually recommend that patients not return to sports that involve pivoting, cutting, and jumping until at least 4 to 9 months after microfracture.
- All patients treated by microfracture for patellofemoral lesions must use a brace set at 0 to 20 degrees for the first 8 weeks postoperatively to limit compression of the regenerating surfaces of the trochlea or patella, or both.

- We allow passive motion with the brace removed, but otherwise the brace must be worn at all times.
- Patients with patellofemoral lesions are placed into a continuous passive motion machine set at 0 to 50 degrees immediately postoperatively.
- Apart from the ROM setting, parameters for the CPM are the same as for tibiofemoral lesions.
- With this regimen, patients typically obtain a pain-free and full passive ROM soon after surgery.
- Patients with lesions of the patellofemoral joint treated by microfracture are allowed to bear weight as tolerated in their brace 2 weeks after surgery.
- After 8 weeks, we open the knee brace gradually before it is discontinued, and then patients are allowed to advance their training progressively.
- Stationary biking without resistance is allowed 2 weeks postoperatively; resistance is added at 8 weeks after microfracture.
- Starting 12 weeks after microfracture, the exercise program is the same as that used for femorotibial lesions.

OUTCOMES

- With appropriate indications, surgical technique, and especially use of our prescribed rehabilitation program, the success rate of microfracture chondroplasty is approximately 90%.3–10
- In a study that followed 72 patients (95% follow-up rate) for an average of 11 years (range, 7–17 years) following microfracture, results showed improvement in symptoms and function in all patients.5
- Patient-reported pain and swelling decreased at postoperative year 1 and continued to decrease at year 2, and clinical improvements were maintained over the study period.
- Age was the only independent predictor of functional (Lysholm) improvement, with patients over 35 years of age improving less than patients under 35; however, both groups showed improvement.
- In National Football League (NFL) players treated with microfracture (FIG 7) between 1986 and 1997, 76% of players returned to play in the NFL the next football season.6

![FIG 6](image1.png)

**FIG 6** • We place great emphasis on patellar mobility and range of motion with instructions to perform medial to lateral and superior to inferior movement of the patella as well as medial to lateral movement of the quadriceps and patellar tendons as shown here.

![FIG 7](image2.png)

**FIG 7** • **A.** A National Football League player presented with a severe defect of the femoral condyle that measured about 5 × 9 cm. This lesion was treated with the microfracture procedure as described here, and the patient was fully compliant with the rehabilitation protocol. **B.** Four months after the microfracture procedure a relook arthroscopy was carried out. The blue arrows show the margins of the lesion, which has been completely filled with repair tissue. **C.** Illustration of how new “repair” cartilage formed over the damaged area.
Those players played an average of 4.6 additional seasons in the NFL.
All players showed decreased symptoms and improvement in function.
Of those players who did not return to play, most had preexisting degenerative changes of the knee.

**COMPLICATIONS**

- Mild transient pain, most often after microfracture in the patellofemoral joint
- A grating or “gritty” sensation of the joint, especially when a patient discontinues use of the knee brace and begins normal weight bearing through a full ROM
- “Catching” or “locking” as the apex of the patella rides over this lesion during joint motion
- Recurrent effusion between 6 and 8 weeks after microfracture, most commonly when beginning to bear weight on the injured leg after microfracture of a defect on the femoral condyle
- Decreased ROM due to secondary scarring

**REFERENCES**

DEFINITION
- Osteochondral autograft “plug” transfer is a technique for treating full-thickness, localized articular cartilage lesions with or without subchondral bone loss in a nonarthritic joint.
- Cylinders or “plugs” of healthy cartilage, with their associated tidemark and subchondral bone, are harvested from one location in the joint and press-fit into same-length recipient holes prepared in the lesion to restore bone contour and the articular surface.
- Multiple plugs may be transferred to the same region, depending on the defect size.

ANATOMY
- Articular cartilage has a complex structure and plays a vital role in normal and athletic activity. It transmits loads uniformly across the joint and provides a smooth, low-friction, gliding surface.
- Articular cartilage is a smooth, viscoelastic, hypocellular structure with a low coefficient of friction (estimated to be 20% of the friction seen with ice on ice) and the ability to withstand significant recurring compressive loads.
- The articular surfaces of diarthroidal joints are covered with hyaline cartilage.
  - Hyaline cartilage is composed of sparsely distributed chondrocytes in a large extracellular matrix made of about 80% water and 20% collagen.
  - Collagen fibers provide form and tensile strength; water gives it substance.
  - Type II collagen accounts for 95% of the total collagen present. The cellular component (chondrocytes) synthesizes and degrades proteoglycans and is the metabolically active portion of this structure.
- Articular cartilage has four distinct zones: a superficial (tangential) zone; a middle (transitional) zone; a deep (radial) zone; and the calcified zone (FIG 1).
  - The superficial zone collagen fibers are oriented parallel to the joint surface and resist both compressive and shear forces. This zone is the thinnest and sometimes is called the gliding zone.
  - The surface layer, known as the lamina splendens, is cell free, and consists mainly of randomly oriented flat bundles of fine collagen fibrils.
  - Under that layer are more densely packed collagen fibers interspersed with elongated, oval chondrocytes oriented parallel to the articular surface.
  - This superficial zone acts as a barrier, limiting the penetration of large molecules into the deeper zone and preventing the loss of molecules from the cartilage into the synovial fluid.
  - The middle (transitional) zone collagen fibers are parallel to the plane of joint motion and resist compressive forces.
- This zone has more proteoglycans and less water and collagen than the superficial zone.
- The chondrocytes are more spherical with more cellular structures, suggesting a matrix synthesis function.
- The deep (radial) zone fibers are perpendicular to the surface and resist both compressive and shear forces.
- The collagen bundles are arranged in a formation known as the arcades of Benninghoff, in which the round chondrocytes are arranged in columns perpendicular to the joint surface.
- The tidemark is located at the base of the deep zone and resists shear stress. It represents a zone of transition from the deep zone to the zone of calcified cartilage.
- The calcified zone acts as an anchor between the articular cartilage and the subchondral bone.
  - It is the deepest zone and is a thin layer of calcified cartilage creating a boundary with the underlying subchondral bone.
  - The cells in this zone usually are smaller and are surrounded by a cartilaginous matrix.

PATHOGENESIS
- Chondral damage can result from a variety of mechanisms, including a pivoting twisting fall, significant direct impacts on the knee, anterior cruciate ligament (ACL) tears, or a patellar dislocation (FIG 2).
ACL injuries cause direct contusions to the articular surfaces and may lead to instability and localized, full-thickness articular cartilage defects.

- Osteochondritis dissecans involves the separation of subchondral bone and cartilage from surrounding healthy tissues.
- It most commonly occurs in the lateral aspect of the medial femoral condyle.
- Traumatic osteochondral lesions include acute bone and cartilage loss due to fracture, crush, or shear injuries.
- Sometimes, even without a clearly remembered traumatic event, the patient develops pain with weight bearing.

NATURAL HISTORY

- Cartilage biopsy samples overlying bone bruises have shown degeneration, necrosis of the chondrocytes, and a loss of proteoglycan.
- An experimental model suggests that a severe bone bruise and its associated chondral necrosis are precursors to degenerative changes.
- Instability secondary to ACL loss has been shown to contribute to the onset of osteoarthritis after ACL tears.
- Articular cartilage has limited regeneration potential.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Various mechanisms of injury are associated with full-thickness articular cartilage lesions, including pivoting twisting falls, direct impacts, and patellar instability.
- Full-thickness chondral lesions often are clinically silent and should be suspected in the setting of any traumatic hemarthrosis, especially with a ligament disruption.
- Reports of pain localized to one compartment, a persistent dull aching pain worsening after activity, and pain most noticeable when falling asleep are common.
- Running, stair climbing, rising from a chair, and squatting may aggravate the symptoms, as does sitting for a prolonged period.
- Physical findings include joint line tenderness, effusion, crepitus, grinding, or catching.
- Effusion is nonspecific but suggests intra-articular pathology.
- Pain on direct palpation of the femoral condyles may indicate cartilage damage.
- Decreased range of motion is nonspecific but often indicates pathology.
- The Lachman test detects ACL instability that may lead to cartilage injury.
- Malalignment of the tibia to the femur when standing may lead to abnormal chondral wear.
- A positive patellar apprehension test signals damage to the medial patellofemoral ligament.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A standard radiographic knee evaluation should be performed.
- This includes standing anteroposterior (AP) views in full extension to identify angular changes and to compare joint space height.
- A 45-degree flexion posteroanterior (PA) weight-bearing view may identify subtle joint space narrowing.
- A non–weight-bearing lateral view obtained in 45-degree flexion in which the posterior femoral condyles overlap, an axial view of both patellae to help evaluate the patellar alignment, and an AP knee flexion view to outline the femoral intercondylar notch also should be obtained.
- Osteochondritis dissecans lesions most commonly are found in the lateral aspect of the medial femoral condyle (FIG 3A) and are best demonstrated on an AP knee flexion view.
- Long-leg hip-to-ankle films accurately determine varus or valgus alignment.
- Proper MRI protocols have high sensitivity and specificity.
- MRI has evolved into a proven tool to evaluate chondral surfaces and detect full- and partial-thickness lesions that may be clinically silent (FIG 3B,C).
Clinical proven cartilage-sensitive sequences include T1-weighted gradient echo with fat suppression and fast spin-echo sequences with and without fat suppression.

Many newer sequences offer promise but have not yet been validated.²²

**DIFFERENTIAL DIAGNOSIS**

- Partial- or full-thickness cartilage lesion
- Osteonecrosis
- Osteochondritis dissecans
- Meniscal tear
- Ligament injuries

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment for full-thickness, discrete chondral lesions consists of physical therapy, anti-inflammatory medication, and activity modification to avoid high-impact or patella-destabilizing activities.
- Bracing options include patellar stabilizing braces for patellofemoral instability and load-shifting braces that unload the injured compartment.
- Unloading the compartment also can be accomplished by shoe inserts that provide an appropriate heel and sole wedge.
- These efforts are more effective for medial femoral condyle lesions than lateral ones.
- It is important to ensure that the patient understands that full-thickness lesions have little spontaneous healing capacity and that further degeneration is likely.

**SURGICAL MANAGEMENT**

- The indications for osteochondral autograft transplantation include discrete, isolated, full-thickness articular cartilage lesions between 1.0 and 2.5 cm in diameter (FIG 4).
- Acceptable results with larger defects have been reported, but not consistently.
- If the depth of subchondral bone loss exceeds 6 mm, it will be necessary to adjust the harvested graft accordingly.
- Contraindications include opposing full-thickness articular cartilage damage (“kissing” lesions), multiple-compartment full-thickness lesions, significant angular changes, history of joint infection, intra-articular fracture, and rheumatoid arthritis.
- This technique is most commonly performed on the femoral condyle; however, osteochondral autograft transplantation of the trochlea, patella, tibial plateau, humerus, and talus has been reported.
- The COR osteochondral repair system (Depuy Mitek, Raynham, MA) allows for the harvesting of a precisely sized osteochondral plug and transplantation into a precisely drilled defect. The technique illustrated here uses this system.
- Other systems have been developed, including the osteochondral autologous transfer system (OATS; Arthrex, Naples, FL), and MosaicPlasty (Smith & Nephew Endoscopy, Andover, MA).

**Preoperative Planning**

- The success of this procedure depends upon maintaining viable chondrocytes. Confocal microscopy studies demonstrate that greater pressure on the articular cartilage cells leads to cell death. Several technical issues are related to greater transplanted cell death. These include high impact pressure during insertion, proud grafts which are not advanced to the level of the adjacent native articular cartilage, and sunken grafts depressed 2 mm or more compared to the adjacent articular cartilage.
- The ideal technique optimizes graft position and stability, provides for consistent graft length harvesting, and minimizes the forces required to insert the grafts.
- Multiple procedures can be performed at the same time, including meniscal repair and ligament reconstruction.
- Improved results occur with concomitant ACL reconstruction.¹⁸
- Any ligament instability or malalignment should be corrected at the time of autografting to avoid increased failure rates.
- All radiographs and MRI images should be reviewed before surgery to confirm whether the lesion can be treated arthroscopically or whether an arthrotomy is needed.
- Perpendicular placement of the harvester and drill to the articular surface is required.
- The COR transfer system has a unique “perpendicularity” guide which enhances the perpendicular harvest of the donor graft as well as the perpendicular orientation of the drilled recipient site.
- Any allograft or synthetic materials that may be needed should be available in the operating room.
- Although allograft tissue avoids concerns about harvest site morbidity, it is offset by the risks of transmitted disease and decreased chondrocyte viability¹⁷ as well as significant costs.

**Positioning**

- Osteochondral autograft transfer in the knee is performed with the patient supine and the operative knee in an arthroscopic leg holder flexed off the table.
- It is crucial to confirm that the knee can be flexed adequately to access the lesion before operative preparation and draping.
- The contralateral leg should be well padded and positioned out of the operative field.
- It may be necessary to drape the operative leg free of a leg holder to obtain enough knee flexion to access the lesion.

**Approach**

- Arthroscopic osteochondral autograft transplantation can be technically difficult, because of the need to achieve perpendicular access to the articular cartilage and adequate knee flexion.

---

**FIG 4** - The indications for osteochondral autograft transplantation include discrete, isolated, full-thickness articular cartilage lesions between 1.0 and 2.5 cm in diameter.
The use of the intercondylar notch as a donor site allows for ready arthroscopic access and avoids the need for an arthrotomy such as is required when obtaining grafts from either the superior medial or lateral femoral condyles above the linea terminalis.

A thorough arthroscopic diagnostic knee evaluation should be performed first.

An arthrotomy can be performed for lesions that cannot be addressed adequately arthroscopically. A spinal needle can be used to determine the best angle for portal creation, ensuring a perpendicular approach to the harvest and defect sites.

Arthroscopic osteochondral autografting includes five steps: lesion evaluation and preparation, determination of the number of grafts needed, defect preparation, graft harvest, and graft delivery.

An adequate synovectomy, especially of the fat pad, is needed to facilitate complete visualization of both the defect and harvest sites.

A spinal needle should be used to identify the correct portal placement for a perpendicular approach.

### Diagnostic Arthroscopy

- During the diagnostic evaluation, a complete examination must be performed to rule out other pathology and confirm that no contraindications to the procedure exist.
- It is necessary to look in the posterior recesses and underneath the menisci for chondral pieces.
- Concomitant ligament surgery should be addressed after the transplantation.

### Lesion Evaluation and Preparation

- A 16-gauge needle can be used to plan the best (perpendicular) approach to both the defect and donor sites.
- The defect is prepared by removing loose debris and freshening the edges with a curette or an arthroscopic knife to create perpendicular chondral walls (TECH FIG 1).
- The subchondral bone should be cleared of any residual articular cartilage, but generalized bone bleeding should be avoided.

**TECH FIG 1** - The defect is prepared by removing loose debris and freshening the edges with a curette or an arthroscopic knife to create perpendicular chondral walls.

### Determining Number of Grafts

- The number of grafts required is planned using the probe to obtain a preliminary measurement of the defect's shape and dimensions (TECH FIG 2A).
- When using more than 1 graft, a 2–3-mm bone bridge should be maintained between the recipient sites to ensure a good press fit.
- The depth of the lesion should be estimated using the 2-mm marks on the harvester.
  - A series of grafts 6 mm in diameter fills the defect best.
  - Larger-plug harvesters are available but may require an arthrotomy and are more likely to encroach on weight-bearing areas at harvest sites.
- Specifically, given that a 10-mm diameter lesion is an indication for grafting, harvesting a 10-mm graft defeats the purpose of using this grafting technique.
- The plan should be to place the grafts starting at the periphery of the defect so that the articular cartilage matches the adjacent chondral edge after transplantation (TECH FIG 2B).
- The depth of the defect also should be analyzed.
- In most cases, the standard 10½–12-mm harvester depth is sufficient to fill the defect.
- Osteochondritis dissecans lesions or those with significant bone loss may require the use of the variable depth harvester and placement of grafts that have cancellous sections standing above the crater base.
DEFECT PREPARATION

- Any residual articular cartilage is removed from the subchondral bone, but generalized bone bleeding should be avoided.
- Drilling the recipient site before harvesting the donor autograft plugs allows the selection of the best match on the femoral surface between the donor grafts and the articular cartilage adjacent to the recipient sites.
- Using the COR perpendicularity system reproducibly identifies the best orientation for drilling the recipient site and makes it feasible to drill the recipient site before harvesting the grafts.
- Insert the drill guide with the perpendicularity rod through the portal and into position at the recipient site. With the drill guide positioned in a perpendicular orientation, turn the perpendicularity rod counterclockwise until it disengages and remove the rod.
- The recipient sites in the defect are drilled with the corresponding size COR drill bit under direct arthroscopic visualization, keeping the drill perpendicular to the articular surface.
  - The projecting tooth at the drill tip keeps the drill from “walking” and allows for precise recipient site placement by creating a starter hole (TECH FIG 3).
- The drill is advanced to the appropriate depth using the markings of 5 mm, 8 mm, 10 mm, 12 mm, 15 mm, and 20 mm found on the side of the drill. This line is compared to the adjacent articular cartilage. The fluted drill’s concave sides remove bone during drilling and reduce both friction and heat.
- In cases of subchondral bone loss, the depth should be used and the depth underdrilled to restore the contour and height of the articular surface.
  - This is accomplished by aligning the laser mark with the desired articular cartilage height.
  - The recipient holes can be drilled at the same time or sequentially after autograft insertion.
  - Care should be taken to maintain a bone bridge between recipient sites of 2 to 3 mm and to avoid recipient site convergence.

GRAFT HARVEST

- Potential harvest sites include the lateral and medial trochlea above the linea terminalis and the intercondylar notch.
  - In general, contact pressures are lower in the intercondylar notch and medial trochlea, but available harvest material is limited.¹
  - Higher contact pressures are found in the lateral trochlea, but these decrease more posteriorly.
- Harvesting 5-mm plugs from the lateral trochlea did not result in significant increases in stress concentration and loading in one study.⁷
- We prefer to harvest from the superior and lateral intercondylar notch, because it commonly is obliterated in ACL reconstruction without subsequent morbidity and allows for an entirely arthroscopic procedure (TECH FIG 4A).
Once the number of plugs to be obtained is determined and the sites prepared, the harvester is inserted into the disposable cutter.

The retropatellar fat pad is completely débrided to improve visualization and avoid soft tissue entrapment.

The COR Harvester Delivery Guide comes with the cutting tool pre-assembled as a single unit. The perpendicularity rod should be inserted into this Harvester/Cutter assembly before insertion into the joint. The perpendicularity rod will function as an obturator and minimize both soft tissue capture and fluid loss as the assembly is inserted into the knee.

The Harvester Delivery Guide/Cutter/perpendicularity rod assembly is positioned on the donor site in preparation for the graft harvest. The perpendicularity rod is used to confirm the perpendicular position of the cutter and then removed.

The arthroscope is rotated to confirm this alignment from several angles.

- Perpendicular grafts can be obtained readily with both arthroscopic and open approaches.4

Using a mallet and continuing to hold the harvester perpendicular to the articular cartilage in all planes, use a mallet to tap the Harvester Delivery Guide/Cutter to the desired depth based upon the 5-mm, 8-mm, 10-mm, 12-mm, 15-mm, and 20-mm markings on the side of the harvester (TECH FIG 4B).

A unique feature of the COR system is the cutter tooth on the harvester which underscores the cancellous bone at the distal end of the harvester tube allowing for a precise and consistent depth cut (TECH FIG 4C).

The T-handle of the harvester is rotated clockwise at least two full rotations, undercutting the distal bone and creating a precise harvest depth.

The plug is removed by gently twisting the T-handle while withdrawing the plug. Care should be taken to avoid toggling the donor hole.

On a firm surface, insert the Harvester Delivery Guide/Cutter into the graft loader and push down firmly until it makes contact with the bottom of the loader. The harvested graft will be pushed from the cancellous bone side through the graft loader (TECH FIG 4D).

**TECH FIG 4** • **A.** Harvest sites include the superior and lateral intercondylar notch, an area that is commonly removed in anterior cruciate ligament reconstruction notchplasty. **B.** Position the Harvester/Delivery Guide/Cutter with the perpendicularity guide on the selected donor site. After verifying the perpendicularity, remove the guide and then tap the harvester until the desired laser line depth has been reached. **C.** A unique feature of the COR system is the cutting tooth which underscores the cancellous bone at the distal end of the harvester tube and allows for a precise depth cut. (B,C: Courtesy of Depuy Mitek, Inc, Raynham, MA.)
of the graft plug upwards into the Harvester/Delivery Guide and out of the cutter section (TECH FIG 5). A loud noise usually accompanies this transfer.

- The harvester is removed from the cutter. The graft plug remains inside the harvester until it is transplanted.
- This transfer system eliminates any loads to the articular surface of the graft and eliminates the danger of chondrocyte damage in this step.

TECH FIG 5 • On a firm surface, insert the Harvester Delivery Guide/Cutter into the graft loader and push down firmly until it makes contact with the bottom of the loader. The harvested graft will be pushed from the cancellous bone side of the graft plug upwards into the Harvester/Delivery Guide and out of the cutter section.

TECH FIG 6 • The loaded harvester–clear plastic delivery guide system is held perpendicular to the articular cartilage and implanted with gentle tapping.

GRAFT INSERTION

- Once the harvester tube is disassembled from the cutter, it is placed in the clear plastic insertion tube with depth markings.
- The plastic plunger is placed in the harvester delivery system before insertion of the delivery system into the joint.
- The loaded harvester–clear plastic delivery guide system is then inserted into the knee. It may be necessary to enlarge the portal slightly to permit this passage.
- The clear end of the delivery system, with the graft tip slightly projecting, is held perpendicularly at the recipient site outlet, and, aligning the articular cartilage of the autograft with the adjacent articular cartilage, implanted with gentle tapping until it is flush with the articular cartilage (TECH FIG 6).
- The Universal tamp may be used to fine-tune the graft placement.
- The 8 mm side is recommended for 4 mm and 6 mm grafts and the 12 mm side is recommended for 8 mm and 10 mm grafts.

MULTIPLE GRAFT REPAIR

If more than one graft is needed to repair an articular cartilage defect, the Harvester/Delivery Guide and Cutter is re-assembled and the process repeated until the defect is completely filled. A 2-mm to 3-mm bone bridge should be maintained between the drilled holes to allow for a secure graft press fit.
POSTOPERATIVE CARE

- Immediate range-of-motion exercises without a brace are begun.
- Non-weight bearing is observed for 3 weeks, followed by progressive weight bearing during weeks 3 to 6 after surgery and then full weight bearing beginning at 6 weeks after surgery.
- A progressive quadriceps strengthening program is then started.
- Full athletic activity is permitted at 4 months.

OUTCOMES

- Condylar lesions typically have excellent clinical results.
- Multiple authors report excellent and good results ranging from 78% to 96% at a minimum of 2 years follow-up.\(^2,6,8,18,19\)
- Patellar or patellar and trochlear mosaicplasties have been reported to have good to excellent results in 79% of patients.\(^9,23\)
- Allograft has been shown to be an effective treatment for patellofemoral disease.\(^14,23\)
- Comparisons of osteochondral transplantation with microfracture, Pridie drilling, and abrasion arthroplasty have shown better results with osteochondral transplantation.\(^5,10\)
- Osteochondral transplantation consistently results in restoration of hyaline cartilage versus “hyaline-like” or fibrocartilage.\(^2,3,6,12\)
- Patients younger than 40 years of age have better results.\(^6,11,18\)

COMPLICATIONS

- Infection
- Loose body if graft loosens
- Graft reabsorption
- Cartilage degeneration due to excessive pressure when seating the graft
- Proud graft leading to excessive contact pressures, graft destruction, and possible “catching” sensation.

REFERENCES

DEFINITION

- Articular cartilage of joints such as the knee is essential to the joint’s normal function, in which it acts as a load-bearing structure and provides a nearly friction-free surface. Unfortunately, articular cartilage is particularly susceptible to traumatic injury or pathologic conditions such as osteochondritis dissecans, which can, over time, be significantly disabling in the young athlete and have the potential of degenerating over time.
- The natural history of articular cartilage injuries is poorly understood.
- The treatment of focal chondral lesions remains a significant challenge for the sports medicine orthopedic surgeon.
- A retrospective review of 31,516 knee arthroscopies examined the prevalence of chondral injuries. This review reported 41% Outerbridge III chondral injuries and 19.2% Outerbridge IV chondral injuries, with an estimated 3% to 4% isolated chondral lesions that were larger than 2 cm².¹³
- The orthopedic surgeon is armed with a variety of surgical treatments for pathologic problems in articular cartilage. Numerous surgical techniques have been proposed to address this difficult and often disabling condition in a young patient population.
- Current articular cartilage resurfacing procedures can be divided into three categories:
  - Bone marrow stimulation
  - Implantation of autologous articular cartilage
  - Transplantation of osteochondral allograft
- The clinical results of all of these surgical procedures have generally good short- and long-term clinical results.²⁻⁵,¹⁴,¹⁹ All have specific drawbacks: for example, marrow stimulation produces fibrocartilage; the autogenous osteochondral autograft transfer system (OATS) has an issue with donor site morbidity; and allograft OATS has a significant risk of disease transmission along with a possible immune response to the allograft tissue.
- In 1994, Brittberg et al⁷ proposed an innovative surgical treatment for articular cartilage injuries, autologous cartilage implantation (ACI).
- ACI is performed in two stages.
  - The initial procedure is a comprehensive arthroscopic evaluation of the articular cartilage defect covering size, location, and depth of lesion (FIG 1).
  - At the same time, if the surgical indications are favorable, the orthopedic surgeon can harvest autologous articular cartilage cells. These articular cartilage cells are then digested enzymatically, with the ultimate isolation of mature chondrocytes.
  - The second stage involves implantation of these autologous chondrocyte cells into the defect through a small knee arthrotomy with a periosteal graft sutured over the defect. The cultured chondrocytes are then injected into the defect beneath the periosteal graft.
- This once-experimental procedure, initially directed toward articular cartilage and used for broad-based indications, has become an important procedure for a specific subset of patients. More than 5000 ACI procedures have been performed in the United States by more than 600 orthopedic surgeons.
- Second-look arthroscopy and biopsy of surgically implanted chondrocytes have documented a reconstitution of the articular surface with similar mechanical properties to the surrounding “hyaline-like articular cartilage,” with documented durability of clinical results.

ANATOMY

- Articular cartilage consists of four distinct histologic zones: superficial, middle, deep, and calcified (FIG 2A).
- The chondrocyte is the cell responsible for the growth of cartilage.
- The metabolic balance of the protein macromolecular complex of articular cartilage is maintained by chondrocytes, which constitute about 5% of the weight of cartilage.
- Water makes up about 75% of the weight of articular cartilage. Water’s role as a cation makes it one of the most important elements.
- Glycosaminoglycans provide the compressive strength of articular cartilage and account for about 10% of cartilage weight. These function to trap and hold water with the articular cartilage.
- Collagen, predominantly type II, provides the form and tensile strength of articular cartilage. It makes up about 10% of the weight of cartilage.

![FIG 1 • Overview of the autogenous cartilage implantation (ACI) technique. Step 1: articular cells are harvested. Step 2: cells are grown in culture for 4 to 6 weeks. Step 3: the lesion is débrided. Step 4: harvested periosteum is sutured onto the defect. Step 5: cultured chondrocyte cells are implanted.]

Sean M. Jones-Quaidoo and Eric W. Carson

Chapter 38
The chondrocyte is the major producer of collagen, proteoglycans, and noncollagenous proteoglycans, as well as enzymes (FIG 2B).

Articular cartilage receives its nutritional supply from the synovial fluid in which it is bathed; it does not have a true blood supply.9

PATHOGENESIS

Injuries of the articular cartilage can result from either trauma, as in the case of a partial- or full-thickness chondral or osteochondral injury, or a pathologic process such as osteochondritis dissecans or local osteonecrosis.

Shallow or partial articular cartilage lesions have limited ability to heal, related primarily to the lack of a blood supply.

An inflammatory response cannot occur, leading to a defect within the articular cartilage.13

In full-thickness chondral lesions, in contrast, there is penetration of the subchondral plate, leading to the migration of progenitor cells from the vasculature in the subchondral bone marrow mesenchymal cells to the surface, an inflammatory response, and an attempted healing response.

The mesenchymal progenitor cells differentiate into fibrocartilage.

This tissue is a weak substitute for hyaline articular cartilage and lacks its resilient mechanical properties.11,20

NATURAL HISTORY

The natural history of articular cartilage injury is poorly understood. It is well recognized, however, that the human body has a limited capacity—or no capacity—to repair articular cartilage injuries.11,20

Limited studies have demonstrated progressive and variable degenerative changes equivalent to those of osteoarthritis.

The repair tissue often succumbs to mechanical stresses with premature degeneration, delamination, interarticular osteophyte formation, and eventual breakdown and joint destruction over time.

Some limited studies have been published with long-term follow-up of untreated osteochondritis dissecans that progressed on to osteoarthritis in adulthood.13

PATIENT HISTORY AND PHYSICAL FINDINGS

Articular cartilage injury can present after a trauma sustained during an athletic event or as a slow progression of symptoms, as in osteochondritis dissecans.

Patients may present with what initially is believed to be meniscal pathology, with swelling, pain, palpable tenderness, and locking of the knee.

Articular cartilage chondral flap or more significant osteochondral injury must be part of the differential diagnosis in evaluating the young patient with knee pain.

Those patients with a more insidious onset and no trauma tend to fit more into the category of osteochondritis dissecans. The findings are more consistent with chronic or recurrent effusion, pain, and mechanical symptoms similar to those of meniscus pathology.

IMAGING AND OTHER DIAGNOSTIC STUDIES

The following plain radiographs are obtained in weight-bearing knee flexion: anteroposterior view; notch view; sunrise view of the patella and trochlea; and lateral views (FIG 3A,B).

Although the articular cartilage itself cannot be appreciated, joint space narrowing and other bony defects will be apparent.

Full-length lower-extremity radiographs are indicated for most patients to assess overall alignment and in consideration of the possibility of performing a realignment procedure concomitantly at the time of the ACI procedure in those patients with malalignment problems.

MRI can more clearly demonstrate articular lesions. As the technology advances, better imaging quality is becoming available.

MRI can assess the size of the lesion, location, involvement of subchondral bone, and number of lesions (FIG 3C).

After ACI, MRI also is being used to assess the degree of defect fill, the integration of the repair cartilage to the subchondral bone plate, and the status of the subchondral bone plate and bone marrow.

Recently, the development of MRI cartilage sequencing has better defined articular cartilage injuries and postoperative osteochondral fill.

T2-weighted MRI mapping techniques give remarkable detail at the proteoglycan level (FIG 3D,E).

Optical coherence tomography (OCT)12 involves cross-sectional imaging technology using near-infrared light technology. The high-resolution images provide a noninvasive look at the microstructural level of articular cartilage.

DIFFERENTIAL DIAGNOSIS

Osteoarthritis

Osteochondritis dissecans
Osteonecrosis
Meniscus injury
Loose body
Chondral flap
Osteochondral injury

NONOPERATIVE MANAGEMENT
- Nonoperative treatment is controversial. Patients without symptoms can be treated nonoperatively, with modification of activity level. This may be effective for a period of time; however, with age there is the potential of developing degenerative arthritis, particularly in those younger patients with large lesions. The true natural history of articular cartilage injuries is not known.
- Some surgeons have proposed aggressive surgical treatment in the hope of preventing degenerative arthritis. Few clinical data are available to support such a treatment algorithm, however.

SURGICAL MANAGEMENT
- Patients who fail conservative treatment for chondral injury must be evaluated for surgical treatment.
- The patient must have a full understanding of the surgical procedure and the extensive rehabilitation it requires.
- The indications for ACI are as follows:
  - Symptomatic weight bearing, unipolar, focal full-thickness chondral injury
  - Cartilage lesions of grade III or IV in the Outerbridge classification
  - Unstable osteochondritis dissecans fragment
  - There is no size restriction on the lesion treated, although lesions typically are larger than 1.5 to 2.0 cm².
  - Physiologic young, active patients who will be compliant with the rehabilitation protocol

- Contraindications
  - Osteoarthritis or bipolar lesions with characteristic radiographic Fairbanks changes:
    - Joint space narrowing
    - Osteophyte formation
    - Subchondral bony sclerosis or cyst formation
  - Comorbidities such as ligamentous instability or meniscal pathology, unless they are addressed either concomitantly with the ACI or in a staged fashion
  - Coexisting inflammatory arthritis or active infections

Preoperative Planning
- The size of the lesion and the availability of adequate cartilage cells for ACI are assessed.
- Any bony deficit is assessed for possible bone grafting at the same time as the ACI. This is especially important for those patients with traumatic osteochondral fractures and large osteochondritis dissecans lesions. These lesions are best evaluated with MRI or at the time of the initial knee arthroscopy and direct examination of the lesion.
- Staged bone grafting can be done at the time of arthroscopic evaluation. In general, 6 months are required between bone grafting and ACI, to allow time for the bone graft to consolidate and recreate a new subchondral plate.
- Alignment of the entire extremity and the status of ligaments and meniscus must be taken into consideration. Biomechanical malalignment, maltracking of the patella, lack of meniscus, and ligament insufficiency are examples of an altered intra-articular environment that can lead to shear stresses, excessive friction, and abnormal compressive loads across the autogenous chondrocyte implantation and thence potentially to failure.
Chapter 38  AUTOGENOUS CARTILAGE IMPLANTATION

- Improvement in ACI results is directly related to recognizing coexisting knee pathology and addressing it, either in a staged procedure or concomitantly at the time of the ACI.
  - For patients with limb malalignment, the surgeon must consider either proximal tibia osteotomies (opening or closing) for varus alignment or, for those with valgus alignment, a distal femoral osteotomy.
  - Most lesions of the patellofemoral joint require distal patella realignment procedures.
  - Ligamentous insufficiency, whether of the ACL, which is most common, or medial or lateral collateral laxity, even the most subtle, may produce excessive shear forces in the knee, which may irreversibly damage the maturing repair tissue produced by ACI. These ligament injuries must be addressed at the time of the ACI.
  - Patients with significant loss of meniscus tissue, through either subtotal or total meniscectomy, must be considered candidates for allograft meniscus transplantation.

Positioning
- The patient is placed on the operating table in the supine position, and the entire lower extremity is steriley prepared and draped so that the knee may be placed in extreme flexion if necessary.
  - A tourniquet is applied to the upper thigh.

Approach
- The first stage of a standard arthroscopy is performed for the harvest of articular cartilage followed by implantation of cells into the chondral defect.
  - A midline incision usually is recommended, followed by a medial or lateral parapatellar arthrotomy to expose the corresponding site of the chondral defect.
  - A separate incision is made or the proximal incision is continued along its distal extent to harvest the periosteal patch on the proximal medial tibia.

ARTHROSCOPIC ASSESSMENT
- Prior to the arthroscopic evaluation, a comprehensive knee examination is performed, with close detail to the ligament stability of the knee and overall alignment.
  - Any ligament instability or malalignment must be addressed either concomitantly or in a staged procedure.
- Taking into account all factors, including the preoperative evaluation, the arthroscopic evaluation of the osteochondral lesion or defect provides the ultimate determination as to whether a patient is a candidate for ACI. Strict attention is paid to the condition of the intra-articular structures, such as integrity of the ligaments and meniscus.
  - Undiagnosed pathology may be critical to the outcome of ACI surgery.

- Complete arthroscopic evaluation of the articular surfaces, both visual and probing (TECH FIG 1), is undertaken.
  - Accurate assessment of the osteochondral lesion, including size (anteroposterior and medial–lateral dimensions), is best obtained with a graduated probe. The estimation of size is of utmost importance with regard to the number of chondrocytes that must be grown in culture to provide optimal fill for the defects.
  - The cartilage injury area is probed for depth, size, number, and location of lesions. Additional assessment determines whether the lesion is a contained or uncontained defect, referring to the borders of the lesion.
  - The Outerbridge system (Table 1) is a practical working approach to arthroscopic grading of articular cartilage defects.
  - A newer, more functional classification has been proposed by the International Cartilage Repair Society (Table 2).

TECH FIG 1  Arthroscopic view of a full-thickness medial femoral condyle lesion.
CARTILAGE BIOPSY FOR AUTOLOGOUS CARTILAGE IMPLANTATION

- A biopsy specimen of cartilage can be obtained at the time of the diagnostic arthroscopy.
- Articular cartilage biopsy sites include the superior medial and lateral femoral condyle, as well as the intercondylar notch.
- The best instrument for harvesting is either a ring curette or a curved notchplasty gauge (TECH FIG 2A).
- The two biopsies should be full-thickness cartilage measuring 5 × 8 mm, with a total weight of 200 to 300 mg (TECH FIG 2B).
- The biopsy specimens are placed in a vial of media in the prepackaged biopsy transport kit from Carticel. This articular cartilage biopsy contains about 200,000 to 300,000 cells, which will be enzymatically digested and grown to approximately 12 million cells per 0.4 mL of culture medium per implanted vial after 4 to 6 weeks, to be used for the implantation procedure.

DEFECT PREPARATION

- After the diagnostic arthroscopy, a medial or lateral parapatellar mini-arthrotomy is performed to provide adequate exposure to the osteochondral defect. If a lesion of the patella or trochlea is present, a formal medial parapatellar arthrotomy with eversion of the patella is done for complete exposure.
- Defect preparation is crucial to the outcome of ACI. All of the unhealthy cartilage surrounding and remaining in the lesion must be débrided completely using a curette and a no. 15 scalpel blade.
- Healthy vertical cartilage borders are necessary for optimal suturing of the periosteum graft (TECH FIG 3A–E).
- The bed of the defect is débrided of fibrous tissue and calcified cartilage, but the subchondral plate must not be violated in the débridement process.
Chapter 38  AUTÓGENOUS CARTILAGE IMPLANTATION

PERIOSTEAL GRAFT HARVEST

- The osteochondral defect is measured with a disposable ruler at its widest mediolateral and superoinferior dimensions.
- An alternative method is to create a template of the lesion with sterile paper, as just described above. The lesion is traced on the paper.
- The proximal medial tibia provides the best site for harvesting periosteum. An alternative site for periosteal tissue is the distal femur.
- The incision is placed 2.5 cm below the pes anserinus (TECH FIG 4A).
- The dissection is carried out down to the periosteum with complete removal of the subcutaneous tissue and fascia. A sharp dissection is recommended to remove this fascia layer.

PERIOSTEUM GRAFT FIXATION

- If a tourniquet has been used, it is deflated at this point, and meticulous hemostasis of the defect bed is undertaken with the techniques described earlier.

- Bleeding at the cartilage defect must be controlled.
  - Three means of controlling bleeding from the subchondral plate are available:
    - Application of sponges soaked in a 1:1000 solution of epinephrine and saline
    - Application of fibrin glue on sites of bleeding on the subchondral bone
    - Use of a needle-point electrocautery with a needle-tip Bovie set on low.
  - Defect dimensions can be measured with a sterile ruler to determine the size of the periosteal patch.
  - The longest anterior to posterior and medial to lateral dimensions should be measured, after which 2 to 3 mm are added to each dimension to obtain the appropriate dimensions for the periosteal graft (TECH FIG 3F).
  - Another method is to make a template from sterile paper from the surgical gloves. A template is placed on the lesion and the defect is outlined with a permanent marking pen, oversizing by 1 to 2 mm. This template is then placed on the proximal tibia as a guide for the periosteal graft.

- With a permanent marker, the template of the lesion is used to outline the periosteum with 2 to 3 mm added to the measured dimensions of the defect to take into account shrinkage of the periosteal graft after removal from the bone.
- The cambium layer is marked to avoid confusion when suturing the periosteum onto the graft with the cambium layer closest to the defect.
- With a no. 15 knife blade cutting sharply down to bone circumferentially, a sharp periosteal elevator is used to elevate the periosteum from the proximal tibia (TECH FIG 4B). It is lifted off the proximal tibia with a smooth pair of pick-ups so as to not damage the cells of the periosteum.
- The periosteum is kept moist with saline.
The orientation of moist periosteal graft on the defect is determined, with the cambium layer closest to the defect. Keeping the periosteum moist is of the utmost importance to preserve the viability of the cambium layer.

Any excess periosteum overlying the borders of the defect must be trimmed to provide an exact fit of the defect.

Once the appropriate orientation and size of the graft are established, the periosteum graft is secured in place with a 6.0 Vicryl suture on a P1 cutting needle using simple interrupted suture technique.

To facilitate easy passage of the suture through the cartilage and thin periosteum, mineral oil or glycerin is applied to the suture.

The four corners of the periosteal graft are first secured and tensioned, followed by sequential sutures about 3 to 4 mm apart from each other (TECH FIG 5A).

This will ensure a watertight seal for the implanted chondrocytes beneath the periosteal graft.

It is critical for the knots of the suture to be placed on the periosteum side to prevent shearing off of the knot and failure of the periosteal graft as the graft is maturing during early rehabilitation.

The suture needle should be passed through the periosteum from outside to inside, approximately 2 mm from the edge of the periosteum.

The needle then is passed through the cartilage using the curvature of the needle, from inside to the outside of the cartilage with the needle entering the cartilage perpendicular to the inside wall of the defect and exiting the articular surface 2 to 3 mm from the débrided defect (TECH FIG 5B,C).

The sutures are placed alternately around the defect, spaced about 3 mm apart, leaving a 5- to 6-mm opening to accommodate an angiocatheter for injection of the chondrocyte cells.

A watertight integrity test is performed with the placement of the 18-gauge catheter into the superior aspect, and saline is slowly infused to assess the graft suturing (TECH FIG 5D).

Areas with saline leakage are reinforced with additional sutures. The area then is retested until the graft is watertight.

Once a watertight seal is obtained, the excess saline is aspirated from the defect.

Commercially prepared fibrin glue, available in most operating rooms, is then passed circumferentially over the periosteum graft—cartilage interface suture line as an additional sealant to prevent leakage of the injected chondrocytes (TECH FIG 5E,F).

**SPECIAL SITUATIONS**

Uncontained defects without vertical cartilage borders on the periphery or encroaching on the intercondylar notch require the use of mini-anchors or suturing into the synovial layer to secure the periosteal graft.

Those osteochondral defects may require bone grafts. Bone graft can be obtained from the proximal tibia or iliac crest in the standard fashion.

This can be done either in a staged fashion or concomitantly at the time of the ACI. Those procedures that are staged can have the bone graft packed into the defect with the plan of returning in 3 months after consolidation. If done concomitantly with ACI, the “periosteal graft sandwich” technique is used. Bone graft is placed in the defect, followed by a periosteal patch. Another periosteal graft is then sutured into place as described previously. The chondrocyte cells are then slowly injected between the two periosteum layers.
Chapter 38  AUTGENOUS CARTILAGE IMPLANTATION

IMPLANTATION OF AUTOGENOUS CHONDROCYTES

- The chondrocyte cells are delivered into the culture medium inside a Carticel vial (Genzyme Biosurgery, Cambridge, MA; TECH FIG 6A).
  - The cells require resuspension in the medium.
  - A sterile 18-gauge catheter is then inserted into the Carticel vial to mix and resuspend the chondrocytes, which settle to the bottom during shipping. This is repeated until the cells are completely resuspended in the medium.
- The cells then are slowly injected under the periosteal patch into the defect.

- After injection of the cells is completed, the needle is withdrawn, and the small opening for the angiocatheter is then sutured with 6.0 Vicryl and sealed with fibrin glue (TECH FIG 6B,C).
- The arthrotomy wound is copiously irrigated, and the retractors are removed slowly. The arthrotomy is then closed in the standard, layered fashion.
- A sterile dressing is applied. No drain is placed in the joint, because the ACI graft may be damaged by the suction of the drain.

PEARLS AND PITFALLS

PEARLS
- Leaving unhealthy cartilage: not excising enough cartilage to define true size of lesion
- Sharp dissection and the taking of bone when harvesting the periosteum
- Not removing the fascia layer off of the periosteum
- Injecting cells before obtaining adequate hemostasis or watertight seal in defect bed
- Attaching the periosteum too low into the lesion
- Tying knots too loosely or on the cartilage rim, or cutting too close to the knot
- Violating the subchondral bone, causing bleeding and potential lysis of implanted chondrocyte cells
- Leaving fibrocartilage in the base of the defect from a previous failed marrow-stimulating procedure
- Not allowing the fibrin glue to congeal before applying it in a drop fashion
- Not harvesting a large enough amount of periosteum. Needs to be oversized by 2 to 3 mm to accommodate for shrinkage

PITFALLS WITH ACI
- Leaving unhealthy cartilage: not excising enough cartilage to define true size of lesion
- Sharp dissection and the taking of bone when harvesting the periosteum
- Not removing the fascia layer off of the periosteum
- Injecting cells before obtaining adequate hemostasis or watertight seal in defect bed
- Attaching the periosteum too low into the lesion
- Tying knots too loosely or on the cartilage rim, or cutting too close to the knot
- Violating the subchondral bone, causing bleeding and potential lysis of implanted chondrocyte cells
- Leaving fibrocartilage in the base of the defect from a previous failed marrow-stimulating procedure
- Not allowing the fibrin glue to congeal before applying it in a drop fashion
- Not harvesting a large enough amount of periosteum. Needs to be oversized by 2 to 3 mm to accommodate for shrinkage

POSTOPERATIVE CARE

- The concept of a slow, gradual time course for healing is critical to understand in post-ACI rehabilitation. The foundation principles of a successful ACI rehabilitation program center on protection of the graft, mobility and motion exercises, muscle strengthening, progressive weight bearing, and patient education.
- Protection of the repaired tissue from excessive intraarticular joint forces is critical during the early postoperative period, although early motion aids in cell orientation of the repaired tissue and prevents arthrofibrosis.
  - If the graft is overloaded with friction and delamination of the ACI tissue, or potential hypertrophy of the ACI tissue occurs, potential complications must be understood.
  - The intraarticular microenvironment must be protective of this complicated interaction of the implanted chondrocytes and the stimulatory aspects of the rehabilitation, such as early motion to allow for the remodeling and maturation of these chondrocytes into a hyaline-like cartilage phenotype.
- During the early phase (day 1 through week 12), the patient is permitted non-weight bearing during weeks 0 to 2, toe-touch weight bearing until weeks 8 to 9, and full weight bearing at 9 weeks.
  - The patient begins continuous passive motion (CPM) 6 to 24 hours after surgery.
  - CPM is performed 6 to 8 hours a day for 6 weeks.
  - The patient should obtain full range of motion.
  - The patient gradually returns to activities of daily living.
- The transition phase is from week 13 through month 6.
  - The patient has increased activities of daily living and increased standing and walking.
  - The patient should have quadricep and hamstring strength greater than 80%.
- The mid-phase is from month 7 through month 9.
  - The patient advances to strength training involving non-pivoting activities.
  - The final phase is month 10 through month 18.
  - The patient can perform low-impact activities, such as skating and cycling, during months 9 through 12; repetitive impact activities such as jogging and aerobic classes during months 13 through 15; and high-level pivoting activities such as tennis and basketball during months 16 through 18.
- Rehabilitation of patellar and trochlear lesions requires special consideration. The contact pressure of the patellofemoral articulation is maximal between 40 and 70 degree of knee flexion; therefore, flexion of this magnitude should be avoided during active knee flexion until the graft is mature and can withstand these shear stresses.
  - Early, gentle patella mobility exercises also are important to prevent adhesions and decreased patella mobility.
  - Avoidance of active knee extension during the first 10 to 12 weeks and the use of continuous passive motion is encouraged to give the best clinical results.
  - The gradual progression of active extension exercises also depends on the size and location of the patellar or trochlear lesion as observed in the operating room.

OUTCOMES

- Brittberg et al7 published their initial results with ACI in The New England Journal of Medicine, a study that revealed impressive initial results. Fourteen of 16 patients (87%) with isolated femoral condyle lesions treated with ACI had good to excellent results with 2-year follow-up. Subsequent follow-up of these patients at 11 years revealed the durability of patient satisfaction with the ACI procedure.6,17,18
- A more recent multicenter study assessed the clinical outcome of lesions of the distal femur treated with ACI in 100 patients.3 Eighty-seven percent of the patients completed a 5-year follow-up assessment. Patients were, on average, 37 years of age and had a mean total defect size of 4.9 cm²; and 70% of the patients had undergone at least one previous articular cartilage procedure. Seventy-three percent showed significant improvement, with an increase of 4.1 points on the Cincinnati knee rating system, substantiating ACI as a viable option for the treatment of chondral injuries.
- Even though ACI is highly successful, new treatment modalities continue to be developed, including an arthroscopic approach and possibly a one-stage procedure.
  - Matrix-induced autologous chondrocyte transplantation (MACI) is one such treatment modality that is conducted arthroscopically (FIG 4).
  - Similar to ACI, autologous chondrocytes are used but are placed into a collagen scaffold for implantation. This construct can be used instead of a periosteal graft, with stabilization still provided with fibrin glue.
  - The scaffold has a porous surface that can embody the repairing tissue. Different scaffolds are under development. Each scaffold must fulfill specific requirements in regard to biocompatibility, endurance, and structural stability. The scaffold should induce maturation and differentiation of the cellular structures that it supports.
  - About 3200 surgical procedures using this technique have been performed in Europe, with excellent early clinical results.1
Chapter 38  AUTOGENOUS CARTILAGE IMPLANTATION

COMPLICATIONS

- Hypertrophy or overgrowth of the periosteum graft
- Delamination of the periosteum graft
- Postoperative stiffness, arthrofibrosis
- Infection
- Donor site morbidity
- Partial or full graft detachment

REFERENCES

FIG 4 • Overview of the matrix-induced autologous chondrocyte transplantation (MACI) technique. Step 1: the defect is assessed and damaged cartilage débrided. Step 2: MACI membrane is cut according to the template, matching defect size and shape. Step 3: proper membrane orientation, in which cells face the bone bed. Step 4: fibrin sealant is applied to the defect and to the bone bed. Step 5: MACI is held in place with light pressure and fixed by fibrin glue, with no suturing required.
DEFINITION

- Articular cartilage lesions are focal, usually isolated, cartilage defects that may be either symptomatic or incidentally found.
- Osteochondritis dissecans is an osteochondral lesion that occurs in adolescents and, therefore, may have different management ramifications from lesions in adults.
- Lesions can be partial- or full-thickness, down to subchondral bone.
- Lesions can be secondary to trauma or atraumatic, as is the case for osteochondritis dissecans.
- Cases with a traumatic etiology may have associated ligamentous or meniscal injury.
- Small full-thickness chondral defects may heal adequately with mechanically inferior fibrocartilage (primarily type I collagen), but larger defects often require cartilage transplant surgery to replace the damaged chondral surface.

ANATOMY

- Articular cartilage is composed primarily of type II collagen.
- Chondrocytes that produce the extracellular matrix are of mesenchymal stem cell origin.
- Osteochondral lesions may occur in all three compartments of the knee.
- Chondral defects after a patellar dislocation may be found on the medial patellar facet or lateral trochlea.
- Classically, osteochondritis dissecans occurs at the lateral aspect of the medial femoral condyle.

PATHOGENESIS

- Osteochondral lesions may be traumatic or may have no known history of trauma.
- Traumatic lesions may be caused by compaction, as with an anterior cruciate ligament tear and lateral-based osteochondral injury, or by a shearing mechanism, as seen with patellar dislocations.
- Articular lesions may be found in young persons, as is the case with osteochondritis dissecans, or in elderly persons, as seen with degenerative lesions.
- The etiology of osteochondritis dissecans is uncertain. Traumatic, inflammatory, developmental, and ischemic causes have all been proposed but not proven.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with focal osteochondral lesions typically are active and young, ranging in age from adolescence to middle age.
- Often, the history does not include a specific traumatic episode. History and physical findings can be subtle.
- Presentation is variable; it may mimic meniscal pathology, with intermittent pain and swelling.
- Condylar defects may present with high-impact loading complaints, whereas patellofemoral defects may produce anterior knee pain–type complaints, with stairs and prolonged sitting causing symptoms.
- Patients with large cartilage lesions who are candidates for osteochondral allograft transplant surgery may have a history of previous knee surgery and previous attempts at cartilage regeneration by other methods (eg, microfracture, autologous chondrocyte implantation, osteochondral autograft transplant).
- Physical findings can be nonspecific and may include joint effusion and painful range of motion.
- Tenderness at the defect, on either the condyle, patellar facets, or trochlea, may be elicited.
- In the case of patellofemoral defects, patellar mobility and apprehension must be assessed.
- Ligament integrity must be determined.
- Mechanical alignment must be assessed, and appropriate imaging studies obtained.
- Failure to identify and address ligamentous deficiency or mechanical malalignment will lead to compromise of restorative cartilage procedures.
- Physical examination of the knee should note the following:
  - Chronic or recurrent effusion associated with, although not predictive of, a chondral lesion
  - Pain at extremes of range of motion (ie, forced flexion or forced extension) may indicate meniscal pathology. An extension block may indicate a displaced meniscus tear.
  - Osteochondral defects may cause decreased flexion via effusion, or may have normal range of motion.
  - An isolated lesion may have point tenderness, although it often is difficult to palpate.
  - Increased patellar mobility may indicate generalized ligamentous laxity, increasing suspicion for patellar instability.
  - Mechanical axis views are obtained if there is any hint of malalignment based on gait and stance analysis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior, lateral, and sunrise views are mandatory to determine overall knee condition, rule out diffuse degenerative arthritis, and assess patellar position within the trochlea.
Large chondral defects may not be visible on plain radiographs, or may have a small radiodense bone fragment attached.

“Notch views” may better define more central lesions.

Long-leg mechanical axis views are mandatory in patients with malalignment on physical examination, and should be considered in all candidates for osteochondral autograft transfer.

MRI is the best modality to determine the presence, size, and location of cartilage lesions, as well as to determine the integrity of menisci and ligaments (FIG 1A–C).

Arthroscopy remains the gold standard for evaluation of articular cartilage lesions (FIG 1D).

**DIFFERENTIAL DIAGNOSIS**

- Meniscal tear
- Degenerative arthritis
- Patellar instability
- Bone contusion
- Avascular necrosis
- Undiagnosed ligamentous injury

**NONOPERATIVE MANAGEMENT**

- Patients with asymptomatic osteochondral lesions (often found incidentally on standard knee arthroscopy) may be candidates for nonoperative treatment.
- Long-term studies may indicate an increased risk for degenerative arthritis with conservative management, but no randomized controlled studies exist.
- Nonoperative treatment should consist of physical therapy to obtain or maintain painless, full range of motion.
- Aggravating impact activities should be avoided.

- Patients may participate in sports as tolerated.
- Unloader braces or shoe wedges may help alleviate mild symptoms.

**SURGICAL MANAGEMENT**

- Osteochondral allograft transplantation often is a two-stage procedure.
- The magnitude of the lesion and occasionally the diagnosis itself often are not appreciated until first-look arthroscopy (FIG 2).
- Size and location of the cartilage lesion is determined.
- Lesions 1 cm in diameter or larger are considered for allograft transplant. Smaller lesions may be amenable to microfracture or autograft cartilage transplant with single or multiple plugs.
Donors are screened with a multifactorial process promoted by the American Association of Tissue Banks to minimize the risk of disease transmission.

**Positioning**
- We prefer to have the patient supine, keeping the foot of the table up.
- A lateral post and sliding footrest or taped sandbag allow for 90-degree flexion positioning of the knee.
- The surgeon should be able to flex the knee to 120 degrees if needed.
- A tourniquet is placed but is inflated only if visualization is compromised by intra-articular bleeding.

**Approach**
- The approach depends on the location of the defect.
- The defect typically is on the medial or lateral femoral condyle, requiring a longitudinal parapatellar tendon arthrotomy.
- Large trochlear or patellar defects amenable to osteochondral allograft transplantation (rare) may require a larger parapatellar incision and eversion of the patella.

**Preoperative Planning**
- Mechanical alignment must be assessed and, if necessary, osteotomy planned for.
- Templated radiographs are obtained for appropriate allograft sizing, based on the medial-lateral dimension of the lesion.
- The patient must be informed that there is no way to predict when an appropriate-sized donor will become available, and that a moderate waiting period (weeks to months) may be required before surgery can be done.
- Fresh osteochondral allografts are used. Frozen chondral grafts are unacceptable.
- Allografts are harvested within 24 hours of donor death and can be preserved for up to 4 days at 4°C.
- Chondrocyte viability likely declines after 5 days, but prolonged storage—up to 21 days—currently is acceptable. After 28 days, chondrocyte viability is unacceptably diminished.
- Tissue matching and immunologic suppression are unnecessary with osteochondral grafts.

**FEMORAL CONDYLE OSTEOCHONDRAL ALLOGRAFT TRANSPLANT**

**Diagnostic Arthroscopy**
- A brief diagnostic arthroscopy is performed to fully assess or reassess the condylar defect (TECH FIG 1A) as well as to examine for additional knee pathology and any changes from the original arthroscopy.

**Sizing**
- The size of the defect is determined using a cannulated cylindrical sizing device.
- A circumferential mark is placed around the sizer to outline the margins of the defect to be grafted (TECH FIG 2A).
- Occasionally, a chondral defect is large or irregularly shaped, and requires more than one allograft. The resultant graft may be in the form of a “snowman,” with two or even three differently sized circular grafts stacked on top of one another.
- A central guide pin is placed through the sizer into bone to a depth of 2 to 3 cm. The sizer is then removed (TECH FIG 2B).
- A reference mark is placed at the superior (12 o’clock) position of the recipient site.

**Recipient Site Preparation**
- The recipient site is prepared by first scoring the periphery of the lesion (TECH FIG 3A).
- Next, a counterbore or reamer is used to drill the defect to a depth of 8 to 10 mm circumferentially, to bleeding subchondral bone (TECH FIG 3B).
- Following that, the recipient bed should be drilled with a small (1.6 to 2.0 mm) drill bit to stimulate additional vascular response (TECH FIG 3C).
- The recipient site depth is then measured in four positions, as on the face of a clock: 12 o’clock, 3 o’clock, 6 o’clock, and 9 o’clock.
Chapter 39 ALLOGRAFT CARTILAGE TRANSPLANTATION

Donor Preparation

- The same sizer used for defect sizing is used to template the allograft hemicondyle on the back table. Careful comparison of defect location (e.g., relative to femoral notch) and donor position is imperative to ensure optimal donor-recipient fit (TECH FIG 4A,B).
- We use the Arthrex Osteochondral Allograft Transfer System (OATS) Workstation (Naples, FL) to help secure the donor graft. This instrument allows for multiple degrees of freedom while positioning and contouring the graft (TECH FIG 4C).
- The angle of harvest of the donor tissue must match the angle at which the recipient site was reamed (TECH FIG 4D).
- Next, the donor osteochondral plug(s) is harvested. The Arthrex system makes it possible to completely drill through the donor condyle, which is held in place with the OATS Workstation. The relevant donor graft tissue is then carefully removed from the harvester drill (TECH FIG 4E,F).

Graft Harvest

- The graft depth is now measured and marked to the precise degree that the recipient bed was measured, in the same four quadrants.
- The graft is held using allograft holding forceps, similar to the manner in which the patella is prepared during total knee arthroplasty. The graft cut is made using a power saw, with care taken to match the cut to the previously made depth measurements. The osteochondral portion of the graft should be held within the forceps, so as not to drop the relevant portion of the graft once the cut is completed (TECH FIG 5A-C).

#### TECH FIG 2 • A. Sizing of osteochondral defect. B. Placement of a central pin through the center of the sizer into the center of the defect after circumferential marking of the sizer on the condyle.

- The depth of the recipient site may not be precisely consistent throughout its circumference. Donor modification will allow for fine tuning.

6 o’clock, and 9 o’clock. This may be done using a standard paper ruler, or by a measuring device supplied by the equipment company (TECH FIG 3D).

#### TECH FIG 3 • A. Scoring of peripheral cartilage. Note placement of the 12 o’clock reference mark. B. Counterbore reaming of a defect, over the central pin, to a depth of 8 to 10 mm. C. Recipient site reamed to subchondral bone and drilled with 2.0-mm drill bit to enhance subchondral bleeding. D. Measuring of defect depth.

TECH FIG 5 • A. Donor plug. B. Sawing of excess subchondral bone to exact depth of four quadrants of recipient site. C. Diagram of sawing excess bone at precise quadrant levels. (continued)
The bony end of the graft’s edges should be slightly rounded, or “bulletized,” to ease insertion of the graft into the recipient socket (TECH FIG 5D,E).

**Delivery**

- Before graft insertion, the recipient bed may be further prepared by using a dilator to widen the socket by 0.5 mm and to smooth the socket surfaces. (This step is optional.)
- The graft is then inserted manually, after lining up the 12 o’clock recipient and donor reference marks (TECH FIG 6A). If the press-fit method is inadequate, an appropriately sized tamp is used to gently tap the graft into position (TECH FIG 6B).
- Additional fixation usually is unnecessary (TECH FIG 6C–E).

**TECH FIG 5** (continued) D. Contouring of osteochondral plug. E. Fully contoured and “bulletized” osteochondral plug.

**TECH FIG 6** A. Manual graft insertion. B. Diagram of insertion using graft delivery tube. C. Final graft, open. D. Final graft, as seen through the arthroscope. E. Three month follow-up, with a second-look arthroscopy.
**POSTOPERATIVE CARE**

- Patients typically are discharged home from same-day surgery.
- An ice cuff about the knee helps alleviate postoperative pain and swelling.
- Bracing is not indicated for isolated OATS.
- Continuous passive motion is begun on day 1 and progressed to full as tolerated; typically 0 to 60 degrees on postoperative day 1, then increased by 5 degrees per day; however, there are no passive range-of-motion restrictions.
- Patients are given strict non-weight-bearing instructions.
- Our preference is strict non-weight bearing for 8 weeks, followed by partial weight bearing for another 4 weeks.
- Patients may be expected to return to full activities by 6 to 8 months.

**OUTCOMES**

- Gross et al² reported on 60 fresh femoral osteochondral allografts at an average of 10 years and 65 fresh tibial plateau osteochondral allografts at 11.8 years (average) with 84% good/excellent results and 86% good/excellent results, respectively, for posttraumatic defects.
- Kaplan-Meier survivorship analysis determined 95% survival at 5 years, 85% at 10 years, and 74% at 15 years for femoral grafts.
- Tibial allografts were reported to have 95% survivorship at 5 years, 80% at 10 years, and 65% at 15 years.
- We determined no negative outcome with meniscal transplant or limb realignment surgery.
- Shasha et al⁷ reported the results of 60 fresh femoral allografts for varying etiologies (ie, posttraumatic, osteoarthritis, osteonecrosis, osteochondritis dissecans) with an average follow-up of 10 years.
- Survivorship data revealed 95% survivorship at 5 years, 85% at 10 years, and 74% at 15 years, with 84% good/excellent results and 12 graft failures.

**COMPLICATIONS**

- Infection
- Stiffness
- Thromboembolic events
- Reflex sympathetic dystrophy
- Graft dislodgment/failure

**REFERENCES**

DEFINITION

- Osteochondritis dissecans (OCD), avascular necrosis (AVN), spontaneous osteonecrosis of the knee, and chondral and osteochondral lesions all occur at or beneath the articular surface of a weight-bearing joint and are easily confused (FIG 1).
- OCD lesions occur when a segment of subchondral bone becomes avascular. The wafer of bone plus the overlying articular cartilage may become separated from the underlying bone.
- Chondral lesions on the articular surface do not penetrate subchondral bone; damage is to chondrocytes and extracellular matrix, and there is no inflammatory healing response.
- Osteochondral lesions not only damage articular cartilage but also penetrate subchondral bone, and, therefore, cause an inflammatory healing response.
- AVN occurs when a larger wedge segment of bone loses its blood supply. If the necrosis extends to the subchondral bone, this can lead to subchondral fracture and bone surface collapse.
- In OCD, the avascular fragment separates from a normal, vascular bony bed beneath a sclerotic rim. In AVN the avascular osteochondral surface breaks into multiple fragments and separates from an avascular bed.

Osteochondritis Dissecans

- OCD lesions most often are found in the knee. They also occur commonly in the capitellum and talus.
- In the knee, OCD lesions involve the medial femoral condyle 80% to 85% of the time, the lateral femoral condyle 10% to 15% of the time, and the trochlea less than 1% of the time. Patellar lesions are uncommon, seen in only 5% to 10% of cases, and typically occur in the inferomedial area.4,7,8
- Classic lesions occur in the lateral aspect of the medial femoral condyle. Lateral lesions most often are located in the inferocentral region and involve a significant portion of the weight-bearing surface (FIG 2).

Avascular Necrosis

- AVN most commonly is seen in the hip. The knee is the second most common location, but accounts for only about 10% as many cases as the hip. AVN can affect the femur, tibia, or both; is bilateral in over 80% of cases; and usually involves multiple condyles (FIG 3A).
- AVN involves a larger area of subchondral bone, with extension into the epiphysis and even the metaphysis or diaphysis.

Spontaneous Osteonecrosis of the Knee

- Spontaneous osteonecrosis of the knee is different from AVN. Spontaneous osteonecrosis of the knee occurs in patients older than 55 years, involves only one condyle (most commonly medial), and is unilateral in 99% of cases (FIG 3B,C).
- The pathologic lesion in spontaneous osteonecrosis of the knee is a stress fracture of subchondral bone with collapse of the articular surface and secondary joint incongruity and pain.

PATHOGENESIS

Osteochondritis Dissecans

- The definitive cause of OCD lesions remains elusive. Several theories exist, including trauma, ischemia, abnormal ossification involving the physis, genetic predisposition, and combinations of these. Prominent theories are further discussed in the following paragraphs, with most authors suspecting that repetitive stress plays a central role.
- Repetitive microtrauma may create a stress fracture within subchondral bone. If the microtrauma continues and overwhelms the ability of the subchondral bone to heal, necrosis may occur, leading to separation and nonunion of the segment.4
- The epiphyseal artery supplies the epiphysis and secondary centers of ossification.
- Repetitive microtrauma or a trauma in a growing child to one of these small end arteries with a tenuous blood supply

FIG 3 • A. MRI scan of AVN involving multiple condyles with extension into the metaphysis. B,C. MRI scans of spontaneous osteonecrosis of the knee involving the medial condyle only. Note the edema adjacent to the involved area.

FIG 4 • Osteochondritis lesions can occur from an interruption of the epiphyseal blood supply to a specific area. (Adapted from Williams JS Jr, Bush-Joseph CA, Bach BR. Osteochondritis dissecans of the knee: a review. Am J Knee Surg 1998;11:221–232.)
can result in disruption of the vascular supply to the segment, with resultant development of an OCD lesion (FIG 4).

- The alteration of subchondral vascularity is precipitated by insult at a vulnerable point.
  - In juvenile cases, revascularization can occur.
  - In most situations, however, healing is inadequate, and persistent avascularity of the fragment, along with mechanical forces at the subchondral region, leads to articular surface fracture.
- Synovial fluid pumped into the bone around the fragment via knee motion limits healing by preventing fibrin clot formation. The pressurized fluid can even erode bone and create a cystic defect. Loss of fragment stability results in loose body formation.
- Shear stress may be created by the medial tibial spine abutting the medial femoral condyle, possibly coupled with traction from the posterior cruciate ligament origin. However, this theory does not account for the presence of lesions at other locations and the fact that tibial eminence impingement does not occur in connection with normal walking or running.

Avascular Necrosis

- AVN of the knee has been called ischemic, idiopathic, or corticosteroid-associated necrosis.
  - As with AVN of the hip, necrotic bone leads to subchondral fracture and subsequent joint collapse.
- Similar to OCD lesions, AVN occurs from interruption of blood supply to a segment of bone, but in AVN the interruption is nontraumatic and may involve the epiphysis and also extend into the metaphysis.

NATURAL HISTORY

Osteochondritis Dissecans

- OCD lesions occur in between 15 and 21 per 100,000 population, with a peak between the ages of 10 and 15 years.
- They are more common in males, by a 5:3 ratio.
- A history of previous knee trauma is seen in 40% to 60% of patients.
- Lesions are bilateral in 15% to 30% of patients, usually prompting evaluation of both knees after making the diagnosis.
  - If lesions are bilateral, they typically are in different phases of development.
- Patient maturity aids in prediction of treatment outcome.
  - Juvenile cases with open physes have a high (65% to 75%) potential to heal.
  - Results in adolescent cases are less predictable. About 50% do go on to heal, but the remainder have a progressive, nonhealing course similar to that of adult (ie, patients with closed physes) patients.
  - In skeletally mature patients, healing potential is essentially nonexistent.
- Factors affecting prognosis include size and site of the lesion, fragment stability, joint fluid behind the fragment, status of the articular surface, and duration of the disorder.

Avascular Necrosis

- AVN of the knee occurs most often in patients younger than 55 years of age, involves multiple condyles, and is bilateral more than 80% of the time.
- Patients have AVN in other large joints in 60% to 90% of cases, are predominantly women, and often have a history of systemic lupus erythematosus, sickle cell disease, alcoholism, or systemic corticosteroid use.
  - In general, only AVN involving the epiphysis is clinically important. Here, loss of structural support can lead to collapse and fragmentation of the overlying joint surface, resulting in a painful arthritic joint (FIG 5).

PATIENT HISTORY AND PHYSICAL FINDINGS

Osteochondritis Dissecans

- Vague, poorly localized complaints of knee pain often are the initial presentation for OCD lesions.
- Swelling is important to note, because an effusion strongly suggests that the fragment is loose to at least some degree.
- Loose or detached lesions may have mechanical symptoms such as crepitus, catching, or locking. These symptoms can mimic meniscal pathology.
- Symptoms tend to progress with time as continued activity causes a stable lesion to become unstable.
■ Quadriceps atrophy may be present as a late finding with chronic lesions.
■ Loss of range of motion is uncommon. Pain with range of motion, crepitus, or mechanical symptoms may represent an unstable lesion.
■ Wilson’s sign is specific for medial femoral condyle lesions and is tested for by flexing the knee to 90 degrees, then internally rotating and slowly extending it.
■ Patients develop pain (positive Wilson’s sign) at approximately 30 degrees as the tibial spine abuts against the medial femoral condyle; pain is relieved with external rotation.
■ According to recent studies, this sign may lack sensitivity.8
■ Patients may walk with an antalgic gait, externally rotating the affected leg to avoid contact of the tibial spine against the medial femoral condyle in the classic lesion.
■ Tenderness to direct palpation of the lesion (Axhausen’s sign) is found in patients with subchondral instability and is a helpful indicator of progressive healing as the sign abates.

Avascular Necrosis
■ Patients with AVN have insidious onset of knee pain.
■ The pain may be medial, lateral, or diffuse.
■ Mild effusions and joint line tenderness may be present.
■ The physical examination often is unremarkable.

IMAGING AND OTHER DIAGNOSTIC STUDIES
Osteochondritis Dissecans
■ In OCD, plain films help to localize and characterize the lesion while also providing valuable information regarding skeletal maturity and age of the lesion, and ruling out other bony injuries.
■ Radiographic evaluation should include anteroposterior (AP), lateral, tunnel, and sunrise views (FIG 6A,B).
■ Tunnel views provide visualization of the femoral condyles in greater profile than can be obtained with AP views (FIG 6C,D). The tunnel view often is the most revealing view.
because OCD lesions commonly are located on the lateral aspect of the medial femoral condyle.

- Comparison views of the opposite knee should be considered, because 15% to 30% of cases are bilateral.
- Children younger than 7 years of age may have irregularities of the distal femoral ossification centers that simulate OCD lesions. These represent anatomic variants of normal ossification and are asymptomatic.
- MRI is an essential part of the diagnostic evaluation of OCD.
- It provides critical information regarding the status of cartilage and subchondral bone, size of the lesion, presence of fluid beneath the lesion, extent of bony edema, as well as loose bodies or other knee injuries (FIG 6E,F).
- DeSmet et al found four MRI criteria that are negatively correlated with the ability of OCD lesions to heal after nonoperative treatment: a line of high signal intensity beneath the lesion, indicating synovial fluid, that (1) is at least 5 mm long; (2) is at least 5 mm thick; or (3) communicates with the joint surface; and (4) a focal defect of 5 mm or more in the articular surface.
- The high-signal line was found in 72% of unstable lesions and was the most common sign in patients who failed nonoperative treatment.
- Historically, Cahill and Berg advocated the use of serial technetium 99m bone scans for evaluation of healing. This recommendation was based on the relation between blood flow and osteoblastic activity with scintigraphic activity.
- Unfortunately, the isotropic tracer remains in the affected area well after healing, making interpretation difficult.
- The use of serial bone scans for the management of OCD lesions has not been universally accepted, in large part because of the need for intravenous access, time required for the study, and, more importantly, the emergence of MRI.

Avascular Necrosis

- For patients with AVN, plain radiographs and MRI scans should be obtained.
- Once the diagnosis of AVN is established, screening MRI of both hips should be considered.

DIFFERENTIAL DIAGNOSIS

- Normal accessory ossification centers
- Loose bodies
- Meniscus pathology
- Acute osteochondral fracture
- Avascular necrosis
- Epiphyseal dysplasia

NONOPERATIVE MANAGEMENT

Osteochondritis Dissecans

- Initial nonoperative treatment is indicated in children with open physis because of the favorable natural history in this patient population.
- Cahill reported that 50% of juvenile OCD lesions will heal within 10 to 18 months if the physis remains open and patient compliance is maintained.
- Most authors agree that 6 weeks of protected weight bearing followed by 6 weeks of activity modification and re-evaluation with radiographs plus MRI at 3 months constitutes an adequate trial of nonoperative treatment.

Children present unique challenges with regard to compliance.

- Some authors advocate use of a knee immobilizer as part of the nonoperative regimen, believing that the combination of a stable lesion, non-weight bearing, knee immobilization, and daily range-of-motion exercises followed by activity modification will result in successful healing by 3 to 6 months in over 90% of cases.
- Although no randomized prospective data have been released to support use of a knee immobilizer, a brace may be useful to increase compliance with the nonoperative regimen in this difficult patient population.
- Nonoperative management rarely is indicated in the symptomatic adult population because of the unremitting course of the disease.

- After closure of the physis, healing capacity is greatly reduced, and the possibility of instability, loosening, and subsequent detachment of the lesion is high.
- Careful evaluation of adolescent patients nearing skeletal maturity is necessary, because their healing ability also is decreased compared to that of younger patients.
- Aggressive and early operative intervention usually is indicated to preserve the integrity of the joint.

Avascular Necrosis

- In AVN, initial treatment with analgesics, nonsteroidal anti-inflammatory medications, and protected weight bearing for 3 months represents an adequate trial of nonoperative management.
- If symptoms persist, surgical intervention should be considered.

SURGICAL MANAGEMENT

Osteochondritis Dissecans

- In OCD, operative treatment goals are to maintain joint congruity, rigidly fix unstable fragments, and repair osteochondral defects, thereby reducing symptoms and preventing additional cartilage deterioration (FIG 7).
- Operative treatment should be performed in skeletally immature patients with unstable or detached lesions, and also in patients who are approaching physeal closure whose lesions have failed nonoperative intervention.
- Surgical intervention in OCD begins with arthroscopy. The stability of the lesion and the integrity of the overlying cartilage can be assessed directly.
- Arthroscopic drilling of juvenile OCD lesions is appropriate in patients who have failed nonoperative management in lesions that remain stable with intact articular surfaces. Drilling aims to create channels for possible revascularization and healing.
- Retrograde drilling across the epiphysis avoids penetration of the articular surface but is technically demanding in terms of drill depth and placement accuracy.
- Antegrade transarticular drilling is straightforward and creates channels that heal with fibrocartilage on the joint surface.
- Arthroscopic drilling and fixation in situ can be performed for stable or minimally unstable lesions without evidence of articular cartilage disruption or fluid behind the fragment on MRI.
Fixation can be accomplished by a variety of open or arthroscopic methods, including Kirschner wires, cannulated screws, headless variable pitch compression screws, bone pegs, and bioabsorbable implants. Nonabsorbable fixation requires an additional surgery for hardware removal.

- Unstable lesions have fibrous tissue and a sclerotic bony rim behind them that is best removed to allow healing to occur (FIG 8). Furthermore, any joint fluid beneath a fragment will prevent formation of a fibrin clot, thereby preventing the first step necessary for bony healing.
- Unstable lesions with subchondral bone loss should be grafted with autogenous bone graft packed into the defect before fragment reduction and subsequent fixation.
- Bone grafting fills any voids that would prevent the fragment from sitting flush with the surrounding articular cartilage. Local autogenous bone graft sources include the distal femur and proximal tibia.
- Patients with completely unstable lesions (loose bodies) that have subchondral bone attached can be trimmed to match the defect, bone grafted, and fixed primarily.
- Several salvage options are available for lesions that cannot be repaired primarily.
- Débridement and lavage are used for incidentally discovered lesions or those not involving a major weight-bearing area in patients with mostly mechanical symptoms. No attempt is made to repair or replace the damaged articular surface.

Marrow-stimulating techniques (eg, drilling, abrasion arthroplasty, or microfracture) promote a healing response in the form of fibrocartilage in the area of the lesion.

Restorative techniques replace damaged areas with new articular cartilage. These include osteochondral autografting, osteochondral allografting, and autologous chondrocyte implantation.

**Avascular Necrosis**

- Surgical treatment of AVN can include arthroscopic débride-ment, arthroscopic drilling, core decompression, or high tibial osteotomy.
- Core decompression has been shown to be relatively successful for symptomatic subchondral lesions prior to collapse.
- Resurfacing with osteoarticular allografts or autografts is not generally favored because the bony bed is dead.
- For patients with collapse and secondary arthrosis, unicompartmental arthroplasty and total knee arthroplasty are additional options.

**Preoperative Planning**

**Osteochondritis Dissecans**

- Plain radiographs should be reviewed for growth plate status, localization of lesion in both AP and lateral planes, presence or absence of sclerosis, and possible loose bodies.
- MRI scans should be reviewed for accurate estimate of lesion size, status of cartilage and subchondral bone, high-signal zone beneath the fragment, bony edema, presence of loose bodies, or concomitant intra-articular pathology. In particular, the presence of joint fluid or cystic erosions behind the fragment determines the need for bone grafting.

**AVASCULAR NECROSIS**

In AVN, plain films evaluate for evidence of collapse and secondary arthrosis (FIG 9). Once present, core decompression is not indicated.

MRI aids in determining the location and extent of subchondral bone involvement. Only lesions extending to subchondral
bone are at risk for collapse and, therefore, appropriate for core decompression.

**Positioning**
- Patients are positioned supine.
- Retrograde drilling of femoral lesions is aided by placing an image intensifier on the opposite side of a radiolucent table to facilitate intraoperative imaging.
- A tourniquet is placed on the operative thigh, and a lateral post is used to stabilize the extremity for valgus stress. The post also facilitates hip rotation in the figure 4 position, allowing lateral knee access and ease in obtaining lateral imaging.
- The extremity is then prepared and draped, the tourniquet is inflated, and diagnostic arthroscopy is performed.

**Approach**
- Lesions may be approached using standard arthroscopic techniques.
- The surgeon should have a low threshold for making a limited medial or lateral arthrotomy for direct access to the lesion. It is crucial to be perpendicular to the lesion for placement of hardware or osteochondral grafting.

**TRANSCHONDRAL DRILLING OF INTACT OCD LESIONS WITH OR WITHOUT FIXATION**
- Drilling can be accomplished using either an antegrade or retrograde technique (TECH FIG 1A).
- Antegrade techniques are technically easier but violate the articular cartilage.
- Retrograde techniques avoid violation of the articular surface but involve the technical challenges of maintaining drill depth and placement accuracy, and also require the use of fluoroscopy. A cannulated anterior cruciate ligament (ACL) guide is useful for guiding Kirschner wire placement.
- First, a thorough diagnostic arthroscopy is completed.
- Careful inspection of the affected condyle is accomplished by varying the degree of knee flexion. Subtle irregularity at the borders of the lesion is looked for; the remaining articular cartilage will appear smooth.
- The lesion is probed along its borders to ensure that there are no discontinuities in the articular cartilage overlying the subchondral bone (TECH FIG 1B). Once the presence of an intact lesion has been verified, several drill holes are made in the lesion using a 0.062-inch Kirschner wire (TECH FIG 1C,D).
TECHNIQUES

The wire must be positioned perpendicular to the surface.
- A soft tissue protector or drill sleeve is used over the wire.
- Surgeons should use whichever portal provides perpendicular access to the lesion, whether anteromedial or anterolateral. Large lesions may require use of both portals to access the entire lesion.
- Drilling to a depth of 1.5 to 2 cm is done to encourage vascular access to the lesion. In skeletally immature patients, careful limitation of depth is essential to avoid penetration of the physis.
- If any motion can be created by pressing against the fragment, or if the patient is approaching skeletal maturity, fixation of the fragment also should be performed.
- Absorbable fixation options include “headed” nails with barbs at the tip to provide compression, our preferred technique (TECH FIG 1E,F); screws, which have more potential to cause joint surface damage; or smooth pins, which require varied angles of insertion to hold the fragment.
- Metal fixation options include lag screws, variable pitch fully threaded screws, or Kirschner wires (less compression).

PRIMAR Y FIXATION AND BONE GRAFTING OF OSTEOCHONDROSIS DISSECSAN S LESIONS

- Primary fixation of OCD lesions of the knee should be attempted whenever possible.
- The presence of subchondral bone on the undersurface of the lesion is a prerequisite for success of primary fixation. A lesion made of cartilage alone will not heal (TECH FIG 2A).
- First, a diagnostic arthroscopy is performed. Once the lesion is identified it is probed and examined for any fibrous tissue in the bed of the lesion.
- The surgeon should have a low threshold for making a mini-arthrotomy for direct access and visualization of the lesion. This facilitates fixation perpendicular to the fragment, thereby maximizing stability and the compression obtained.
- Mini-arthrotomies can be made by extension of the anteromedial or anterolateral portal, depending on the location of the lesion. Care must be taken to avoid injury to the anterior horn of the meniscus during distal extension of the arthrotomy.
- A limited fat pad excision is helpful to improve visualization.
- Anterior and posterior lesions can be visualized by varying extention or flexion of the knee.
- A curette is used to remove fibrous tissue from both the bed and the undersurface of the lesion until exposed bleeding bone is seen. The arthroscopic burr can help penetrate the dense sclerotic rim.
- Reduction of the fragment is then performed either manually or with Kirschner wires.
- It is imperative that the reduction sit flush with the articular surface.
- Any stepoff will result in increased contact stress and shear forces secondary to surface irregularity, with resultant edge loading.
Bone grafting is essential, therefore, to avoid malreduction of the fragment.

Cancellous autograft can be harvested from local sources such as Gerdy’s tubercle on the tibia, or the outer aspect of the distal femur below the physis.

In both cases the periosteum is incised, and then a small cortical window is made with an osteotome. A curette is used to harvest the cancellous bone.

The cortical window is then replaced, and the periosteum is repaired over the defect.

The bone graft is impacted into the bed, followed by repeat reduction and assessment of the chondral surface.

Fixation is achieved by placing the device perpendicular to the surface.

Screw heads should be countersunk beneath the chondral surface to avoid hardware problems.

Multiple fixation points may be necessary, depending on the size of the lesion.

Combining types or techniques of fixation is acceptable. For instance, a compression screw may be placed centrally in a lesion surrounded by absorbable pins at the periphery of the lesion to enhance fixation. Also, if only a portion of the lesion has subchondral bone attached, it is acceptable to fix that portion of the lesion and use osteochondral plug autografts to fill the remainder of the defect (TECH FIG 2B).

Overtightening of screws used for fixation must be avoided. Overly aggressive compression can fracture the fragment.

Final inspection should demonstrate a congruent reduction with secure fixation of the lesion.

Either an antegrade or a retrograde technique can be used in the femur.

Retrograde Drilling of the Femur

Retrograde techniques are preferred because they permit creation of a larger channel for a more effective core decompression.

Retrograde drilling of femoral lesions requires fluoroscopy plus arthroscopy.

A 2.4-mm guidewire is used to pierce from skin down to bone.

The starting point is verified with fluoroscopy in both the AP and lateral planes.

The guidewire is advanced to within 1–2 mm of the articular surface (TECH FIG 3A).

Position of the wire is confirmed on the lateral projection by placing a probe against the target condyle’s distal articular surface. This technique helps avoid confusion created by overlapping shadows when identifying the target condyle (TECH FIG 3B).
Arthroscopic visualization is then used to advance the guidewire to barely pierce the articular surface.

Drilling decompression is performed with a 4.5-mm cannulated drill bit (Endobutton drill bit, Smith & Nephew, Andover, MA) placed over the guidewire.

As it approaches the articular surface, the drill bit should be advanced by hand for better control.
- The drill bit is stopped 2 mm short of the articular surface (TECH FIG 3C,D).
- Two or three passes with the guidewire and cannulated drill bit are required for each lesion.

Antegrade Drilling of the Femur
- Antegrade drilling of femoral lesions involves drilling from the articular surface into the lesion.
- It does not require fluoroscopy.
- Lesions are localized by correlation of arthroscopic findings with MRI images.
- Multiple drill holes are made directly into the lesion using a smooth, 1- to 2-mm guidewire to a depth that penetrates through the lesion and into healthy bone.
- The drilled tract is then aspirated for bleeding using the shaver with suction.
- This bleeding indicates decompression and is evidence that the guidewire passed completely through the necrotic subchondral bone (TECH FIG 4).

Retrograde Drilling of the Tibia
- Tibial lesions are drilled using a retrograde technique.
- Fluoroscopy is optional.
- An ACL guide is used to target the lesion (TECH FIG 5A).
- Lesions are localized by correlation of arthroscopic findings with MRI images.
- A 2.4-mm guidewire is placed through the ACL guide and allowed to just pierce the articular surface (TECH FIG 5B).
- A 4.5-mm drill bit is then used for drilling decompression, stopping the drill bit just beneath the articular surface.

Motorized shaver with suction can be used to aspirate the drill tract for bleeding using the antegrade technique. (Reprinted with permission from Diduch DR, Hampton BJ. Avascular necrosis drilling in the knee. In: Miller MD, Cole BJ, eds. Textbook of arthroscopy. Philadelphia: Elsevier, 2004:593–599.)
**PEARLS AND PITFALLS**

### Mistakes to avoid when treating OCD
- Underestimating instability of the lesion and drilling in situ when fixation of the fragment is necessary for healing to occur.
- Underestimating fluid behind the fragment and pinning in situ when fixation and bone grafting are necessary for healing.
- Excision alone of a fragment with subchondral bone on its undersurface when reduction and fixation are necessary.
- Attempting fixation of a fragment that consists of cartilage only. Without subchondral bone, healing will not occur.
- If in doubt, a mini-arthrotomy should be made for direct access and visualization of the lesion. This facilitates perpendicular fixation, which maximizes healing potential.

### Mistakes to avoid when treating AVN
- Overtreatment of MRI findings. AVN is not always the source of the patient’s pain. Look for other pathology in the knee that may account for the patient’s symptoms. Only lesions with involvement of subchondral bone with potential for subsequent collapse are clinically relevant.
- Drilling of AVN lesions should not be abandoned if initial attempts fail. Repeat drilling is effective in 60% of cases.\(^5\)

---

### POSTOPERATIVE CARE

**Osteochondritis Dissecans**
- After transchondral drilling, with or without fixation of intact OCD lesions, full range-of-motion and closed chain resistance exercises are encouraged.
- Daily range-of-motion exercises are encouraged, because motion is important to provide articular cartilage nutrition via synovial fluid diffusion.
  - Touch-down weight bearing is done for 6 weeks.
  - Advanced weight-bearing and resistance exercises are done from 6 to 12 weeks.
  - Sports or running is avoided until 3 months or radiographic union.
  - Patient compliance is an issue owing to the minimally invasive nature of the surgery.
- After primary fixation and bone grafting of OCD lesions, patients may be placed in a hinged knee brace that is unlocked for self-guided exercises.
  - A continuous passive motion machine may be used for 2 to 3 weeks to help achieve motion.
  - Physical therapy is focused on range of motion for the first 2 weeks, after which gentle, progressive strengthening is initiated.
  - Touch-down weight bearing is permitted during the first 6 weeks, followed by progressive weight bearing.
  - Radiographs are taken 1 to 2 weeks after surgery and on successive visits every 4 weeks thereafter.
  - Once healing is verified radiographically, the patient may be taken back to surgery for hardware removal if necessary. The chondral surface can be inspected and the stability of the lesion can be evaluated at that time.
  - Most authors recommend removal of any metal hardware on the joint surface to minimize secondary wear or possible corrosion from synovial fluid.
  - Return to sports or running usually is not permitted until 6 months after surgery, unless radiographic union is demonstrated before that point.

**Avascular Necrosis**
- After drilling of AVN, patients are limited to 50% weight bearing for 2 weeks, until repeat radiographs are taken to rule out collapse.
- Once collapse is ruled out, weight bearing can be advanced as tolerated.
- Patients may benefit from physical therapy three times a week for 4 weeks. Therapy should focus on quadriceps strengthening and both active and passive range of motion.

### OUTCOMES

**Osteochondritis Dissecans**
- Many authors have found transchondral drilling to be effective in treating OCD lesions in skeletally immature patients. Results are less effective in patients with closed physes.
  - Anderson et al used transchondral drilling to treat 17 patients (20 knees) with open physes and 4 patients with closed physes. The open physes group had a 90% healing rate, whereas the skeletally mature group had a healing rate of 50%.
  - At Children’s Hospital of Philadelphia, 51 patients up to 18 years of age were treated with transchondral drilling. Skeletally immature patients had an 83% success rate, as opposed to 75% success in patients with closed physes. Failure to heal was associated with lesions in nonclassic locations, multiple lesions, and other underlying medical conditions.
  - Aglietti et al noted radiographic healing in 16 knees, and all patients were asymptomatic at follow-up of 4 years.
  - Kocher et al reported on 23 patients (30 knees) treated with transchondral drilling with a follow-up of 3.9 years. Radiographic healing was seen in all patients at an average of 4.4 months. Patients also had significant improvement in Lysholm scores.
  - Primary fixation of OCD lesions has had positive results.
  - Johnson et al treated 35 patients with an arthroscopically assisted technique that employed cannulated screw fixation of the fragment. Results were good or excellent in 90% of cases.
  - Zuniga et al treated 11 patients with symptomatic OCD lesions of the medial femoral condyle with a combination of Herbert screws and absorbable pins. Radiographic signs of healing correlated with the clinical outcome, which was good or excellent in 81.8% of patients.
  - Cugat et al used cannulated screws for fixation of OCD lesions in 14 patients. All patients returned to their previous sporting activity 3 to 11 months after surgery.
Avascular Necrosis

- Treatment of symptomatic AVN with nonoperative methods such as restricted weight bearing, analgesics, and observation has a clinical failure rate higher than 80%.
  - Core decompression of stage I, II, or III knees (Table 1) provides symptomatic relief, with 79% of patients having good or excellent Knee Society scores at 7 years.
  - For patients who fail initial core decompression, repeat decompression and arthroscopic débridement provides some benefit, with results comparable to those of the initial decompression.
  - Core decompression will not improve symptoms once collapse has occurred, because the joint surface then is irregular and essentially arthritic.

COMPLICATIONS

- Nonunion with loose body formation
- Persistent symptomatic lesions
- Inability to localize the lesion
- Drill bit penetration of the articular surface
- Synovitis or foreign body reactions with absorbable implants
- Postoperative knee stiffness
- Hardware migration or failure
- Damage to adjacent articular surfaces

REFERENCES

DEFINITION

Anterior cruciate ligament (ACL) injuries result in a disruption of the fibers of this ligament and an ACL-deficient knee. Although most injuries are complete, partial injuries have been described. In our practice, partial injuries—defined as an asymmetrical Lachman test (or 3 to 4 mm of asymmetry on KT-1000 testing) with a negative pivot shift test during examination under anesthesia, or a one-bundle ACL disruption seen arthroscopically—are rare. The key point in determining how to treat partial injuries is to determine whether functional stability of the ACL has been maintained.

ANATOMY

- The ACL is about 33 mm long and 11 mm in diameter. It is composed of two “bundles”—a more important posterolateral portion, which is tight in extension, and a less critical anteromedial portion, which is tight in flexion.
- It is composed of 90% type I collagen; the remaining collagen is predominantly type III.
- The main blood supply for the ACL is the middle geniculate artery. Mechanoreceptor nerve endings have been identified within the ACL and are thought to have a proprioceptive role.

PATHOGENESIS

ACL injuries usually result from a noncontact pivoting injury, typically involving a change of direction or deceleration maneuver. Patients often describe hearing or feeling a “pop” and will develop an acute or subacute effusion (ie, “swells up like a balloon”). In most cases, the athlete will not be able to return to play and may need assistance to leave the field or slope (we have termed the latter a “positive ski patrol sign”). Combined ACL, medial collateral ligament (MCL), and meniscal injuries have been referred to as the “unhappy triad.”

- Lateral meniscal tears are more common in acute ACL injuries.

NATURAL HISTORY

Researchers from Kaiser Permanente in Southern California, including Donald Fithian and the late Dale Daniel, have done much to contribute to our knowledge of the natural history of the ACL-injured knee.
- From their work, we recognize that patients with a high level of participation in jumping or cutting sports and significant side-to-side differences (>5 mm) on KT-1000 arthrometer measurements are at high risk for recurrent injury without ACL reconstruction.
- Unfortunately, these same researchers have shown an increased incidence of arthritis in the surgically reconstructed ACL group.
- The difficulty with these and other studies is that multiple variables are involved, making comparisons difficult and possibly inaccurate.
- It is clear from the literature that the incidence of meniscal tears and chondral injury can be reduced with ACL reconstruction. Advocates of double-bundle ACL reconstruction propose that the incidence of arthritis may be reduced with this technique, but that theory has yet to be proved clinically.

PHYSICAL FINDINGS

Physical examination methods include the following:

- Effusion: about 70% of acute hemarthrosis cases represent ACL. Range of motion (ROM): loss of extension may be a result of a displaced bucket handle meniscal tear or arthrofibrosis (stiff knee). Loss of flexion may be related to a knee effusion.
- The Lachman test is highly sensitive for ACL deficiency. The patient must relax for this examination, and effusion or a displaced meniscal tear may give a false endpoint.
- The anterior drawer test is poorly sensitive and outdated, but is helpful to rule out a posterior cruciate ligament (PCL) injury.
- The pivot shift test is difficult to perform in the clinic setting, but is an especially helpful and sensitive test during examination under anesthesia.

A complete examination of the knee also should include evaluation of associated injuries and ruling out differential diagnoses, including (but not limited to) the following:

- Meniscal tears: joint line tenderness, pain or popping with provocative maneuvers (eg, McMurray, Apley compression, duck walk), and loss of full extension may be present.
- PCL injury: a “pseudo-Lachman” may be appreciated if the PCL is present, and the unwary examiner may falsely attribute this to an ACL injury. The key is the starting point on the drawer examination. The tibial stepoff in PCL-injured knees will be absent, or the tibia may actually be displaced (or be displaceable) posteriorly, signifying a PCL injury.
- Posterolateral corner (PLC) injury: Injury to the popliteus, popliteofibular ligament, biceps, iliobibial band, or posterior capsule will result in external rotation asymmetry (dial test), a positive posterolateral drawer test, and external rotation recurvatum.
Collateral ligament injury: MCL injuries are recognized as opening with valgus force, and lateral collateral ligament (LCL) injuries open with varus stress. These examinations are tested in both 30 and 0 degrees of knee flexion. Opening to valgus or varus stress in 0 degrees (ie, full extension) signifies a more severe injury, usually involving one or both cruciate ligaments.

Patellar instability: localized tenderness or instability with apprehension testing is essential to rule out a patellar dislocation that reduced spontaneously. This type of injury also can cause an acute knee effusion and can be easily confused with an acute ACL injury.

IMAGING AND DIAGNOSTIC STUDIES

Plain radiographs, including anteroposterior, lateral, and patellar views, should be obtained to rule out bony avulsion fractures or associated injuries.

A small avulsion fracture off the lateral tibial plateau (FIG 1A) represents a lateral capsular avulsion (Segond sign) and is highly associated with an ACL injury. It is very specific, but not sensitive.

Flexion weight-bearing radiographs are important in older or posttraumatic patients to rule out associated osteoarthritis.

Long-leg hip-to-ankle radiographs must be obtained in patients with varus or valgus malalignment.

An osteotomy should be performed before ACL reconstruction in select cases.

MRI is highly sensitive and specific in diagnosing ACL tears as well as associated injuries.

Bone contusions, or bruises, also may be detected in the mid-lateral portion of the lateral femoral condyle (near the sulcus terminalis) and the posterior tibial plateau (FIG 1B).

DIFFERENTIAL DIAGNOSIS

- Meniscal tear
- Osteochondral injury
- Contusion
- Patellar dislocation
- Other ligament/capsular injury (eg, MCL, LCL, PLC, multiple ligament injury)

NONOPERATIVE MANAGEMENT

Although nonoperative management is controversial, patients with less laxity and those who are less involved with high-level pivoting sports may be treated nonoperatively.

Nonoperative treatment is done in three phases over a period of about 3 months.

- In the initial phase, emphasis is placed on regaining full motion, controlling effusion, and maintaining quadriceps tone. (This is appropriate for patients who are surgical candidates as well.)
- In the second phase, quadriceps and hamstring strengthening is emphasized.
- In the third and final phase, sport-specific rehabilitation is accomplished.

Patients may attempt to return to sports after their effusion has completely resolved, they have full ROM, their quadriceps tone and strength have been restored (isokinetic testing is
Patellar tendon grafts (TECH FIG 1) are harvested through a 5- to 7-cm paramedian incision.

- Saphenous nerve branches are protected if identified.
- The paratenon is incised vertically and reflected off the underlying tendon.
- The central third of the tendon (typically 10 mm) is harvested, with care taken not to cut across the longitudinal fibers of the tendon.
- Bone blocks (approximately 25 mm long) are obtained using a micro oscillating saw.
- Care is taken to saw no deeper than 10 mm, particularly on the patellar side, to avoid an iatrogenic fracture.

The tibial bone block can be either more rectangular or more trapezoidal in cross section.

- The patellar bone block should be more triangular in cross section, to avoid injury to the patella.
- The bone blocks are removed using a curved osteotome (again, being careful on the tibial side) and taken to the back table for preparation.
- A rongeur or burr is used to fashion the bone blocks so that they will fit through an appropriately sized tunnel.
- With retraction, the lower portion of the incision can be used to prepare the tibial tunnel.
- If the tendon is harvested at the beginning of the procedure, arthroscopic portals can be made through the incision.

(hamstring) autograft. We use both patellar tendon and hamstring grafts and have found that certain parameters are helpful in determining graft choice (Table 1).

- Other graft choices include quadriceps tendon autograft and a variety of allografts. Although these grafts may be useful in certain cases, they are not popular choices for most surgeons.

- After the graft is selected, the procedure involves arthroscopic diagnosis and repair of pathology, tibial and femoral tunnel placement, graft passage and fixation, and wound closure.

**TECH FIG 1 -** Patellar tendon graft harvesting. A. Exposure of the patellar tendon and paratenon. B. The middle third (~10 mm) of the patellar tendon is measured. (continued)
Hamstring grafts (TECH FIG 2) are harvested through a 2- to 3-cm paramedian incision centered at the level of the tibial tubercle, approximately 6 cm below the medial joint line.

- The sartorial fascia is exposed, and the tendons are palpated.
- The tendons insert in an oblique fashion and are more horizontal than vertical.
- The gracilis tendon insertion is superior to the semitendinosus tendon insertion, but both tendons converge at the pes anserine.
- It is necessary to reflect the overlying sartorial fascia that covers both tendons.
- Alternatively, the tendons can be exposed from their deep side if their insertions are sharply reflected off the tibia.
- Once the tendons are identified, a whipstitch is placed in them near their insertions so that they can be reflected off their insertions and mobilized.

- Blunt dissection and palpation are essential in mobilizing the tendons.
- Both tendons must be mobilized and all tendinous slips freed.
- The semitendinosus will have one or more large bands that attach to the medial head of the gastrocnemius. These must be incised before a tendon stripper is used, or the tendon will be inadvertently cut at this location.
- After harvesting, the tendons are prepared on the back table.
- Muscle fibers are removed from the tendons using a curette or elevator, a whipstitch is placed in the free end, and the tendons are tensioned using a commercially available graft board.
- The grafts are folded in half and the diameter of the four-strand graft measured before tensioning.
- The harvest incision can easily be used for tibial tunnel placement.
- Standard arthroscopic portals are made through the skin at the level of the joint.
ARTHROSCOPY

- Diagnostic arthroscopy is completed, and all pathology is identified.
- Meniscal tears are repaired if possible.
- Articular cartilage lesions are addressed.
- Loose bodies that are identified are removed.
- The ACL is visualized and, if torn, it is débrided with baskets and a shaver.
- The tibial footprint of the ACL and the “over-the-top” position in the back of the notch are cleared of all soft tissue (TECH FIG 3).
- Although most surgeons no longer perform an aggressive notchplasty, it is important to clear enough soft tissue and bone to identify all landmarks and to ensure that the graft will not be impinged upon.
- It also is important to ensure that the roof of the notch will not impinge on the graft. (This is more important in hamstring reconstructions because the anterior portion of the graft may be more easily impinged.)

TECH FIG 3 • A. Remnant ACL tissue is débrided with a combination of arthroscopic shaver, scissors, osteotome, and electrocautery. B. Notchplasty is performed with a combination of a 1/4-inch curved osteotome, mallet, and grasper, or with a spherical motorized burr. Some patients may require minimal or even no notchplasty. The goal is to have enough space for graft placement and visualization purposes. Notchplasty should not extend cephalad to the intercondylar apex. A 3- to 5-mm notchplasty usually is performed, depending on the width of the intercondylar notch. C. The torn ACL. D. Notchplasty is performed. E. Careful débridement of the notch is done before drilling tunnels. F. Notchplasty/débridement of the ACL stump.
TIBIAL TUNNEL PLACEMENT

- A commercially available guide is used to place a guidewire for the tibial tunnel.
- The intra-articular landmarks for the tibial tunnel are as follows (TECH FIG 4):
  - Posteromedial aspect of the ACL footprint
  - Adjacent to the slope of the medial eminence
  - Along a line extended from the posterior border of the anterior horn of the lateral meniscus
  - 7 mm in front of the PCL
- The extra-articular portion of the guide should be positioned midway between the tibial tubercle and the posteromedial aspect of the tibia.\(^5\)
- For patellar tendon reconstructions, the angle of the guide should be set based on the “N + 7 rule”\(^9\) and checked based on the “N + 2 rule.”\(^12\)
  That is, the guide is provisionally set at an angle that is 7 degrees more that the tendon length (in mm) between the bone blocks, and the distance is checked on the plunger for the guide—it should be 2 mm longer than the tendon length. The guide is set between 45 and 50 degrees for hamstring grafts.
- Once the guidewire is placed and checked, a cannulated drill is used to complete the tibial tunnel.
- We use a fully threaded drill bit and save the bone graft that collects in the flutes of the drill to fill the patellar defect (it usually is discarded for hamstring graft reconstructions).
- The PCL is protected with a curette during final tunnel drilling.
- The back edge of the tibial tunnel is rasped to keep the graft from being abraded.

TECH FIG 4 • A. Tibial targeting guide set at N + 7. B. Arthroscopic view of ACL tibial tunnel guide pin placement. C. Fluted reamer showing collected bone graft following tibial tunnel drilling. D. Tibial pin placement usually is performed at an angle 10 degrees greater than the graft–soft tissue construct. For example, a 45-mm soft tissue construct usually is drilled at 55 degrees. This illustration demonstrates that if a steeper angle is selected, it may be more difficult to place the femoral tunnel anatomically.

FEMORAL TUNNEL PLACEMENT

- An endoscopic offset guide is placed through the tibial tunnel and off the back of the posterolateral notch (TECH FIG 5). Some surgeons prefer to place this guide through the medial portal with the knee hyperflexed.
- The guide pin should be placed in the 10:30 (right knee) or 1:30 (left knee) position. (While looking arthroscopically, the top of the notch is the 12:00 position.)
- The offset guide should be chosen to retain a 1-mm posterior wall following drilling. A 10-mm tunnel should be
GRAFT PASSAGE AND FIXATION

- A Beath needle is placed through both tunnels and pierces the quadriceps muscles and skin.
- Sutures from the graft or fixation device are pulled through the tunnels and outside the thigh.
- The graft is pulled into both tunnels and fixed with an interference screw or a fixation device of the surgeon’s choice.
- Once the femoral side is fixed, the knee is cycled through the complete ROM, and the graft is tensioned.
- The tibial side is then fixed with an interference screw or secured to the tibia with a screw and washer or staple (TECH FIG 6).
- The graft is probed and inspected before wound closure is performed.

made with a 6-mm offset guide, because the guide is used to place a guidewire for the center of the tunnel and the radius of a 10-mm drill is 5 mm.
- The femoral tunnel is drilled to a depth of approximately 30 mm for a patellar tendon graft and to within 5 to 8 mm of the far cortex for a hamstring graft.
- Depending on the surgeon’s choice for femoral graft fixation, additional tunnel preparation may be necessary.
- For Endobutton (Smith & Nephew Arthroscopy, Andover, MA) fixation, a 4.5-mm tunnel is drilled through the far cortex.
- For TransFix (Arthrex, Naples, FL), Bone Mulch (Arthrotek, Warsaw, IN), Rigid Fix (DePuy Mitek, Norwood, MA), and other similar fixation systems, transverse pilot holes are created from lateral to medial.
**WOUND CLOSURE**

- The wounds are closed in layers.
- Bone graft from the drill bit or bone block preparation is packed into the patellar defect, and the paratenon is closed for patellar tendon graft cases.
- The sartorial fascia is closed for hamstring graft cases.
- Subcutaneous tissue and skin are closed in standard fashion.

</tbody>
</table>
**POSTOPERATIVE CARE**

- Radiographs are evaluated to ensure that graft placement and fixation are appropriate (FIG 3).
- Some surgeons place the patient in a knee immobilizer or a hinged brace, but we have found that this may restrict their motion and does not provide any benefit.
- Early range of motion (especially extension) is emphasized.
- It is important that a pillow be placed under the heel (not under the knee, which is more comfortable), beginning in the recovery room.
- Closed-chain rehabilitation (beginning with a stationary cycle) is emphasized in the early postoperative course.
- Running typically is delayed until 3 or 4 months postoperatively, and most athletes can return to their sport by 6 months.

**OUTCOMES**

- With appropriate indications and surgical technique, success rates for ACL reconstruction are on the order of 90% to 95%.
- In one study, 96% of patients had KT-1000 side-to-side differences of less than 5 mm. ²
- Comparisons between patellar tendon and hamstring reconstruction have yielded equivalent results.
- Some studies suggest that hamstring grafts may have slightly increased laxity (1 to 2 mm) compared with patellar grafts.
- Other studies have cited an increased incidence of anterior knee pain following ACL reconstruction with patellar tendon grafts.

**COMPLICATIONS**

- Intraoperative graft mishandling ⁴
- Knee flexion must not change following guide pin placement.
- A few degrees of flexion may result in the guidewire bending and shearing by the drill.

- Fixation problems
  - Interference screws must be inserted along the path of the tunnel to avoid divergence.
  - For the femoral tunnel, the surgeon should hyperflex the knee and drop his or her hand toward the tibia while inserting the screw.
  - Intraoperative radiographs should be taken so that problems may be recognized and fixed before leaving the operating room.

**REFERENCES**

DEFINITION
- Anterior cruciate ligament (ACL) tears have been described in detail in Chapter SM-41.
- Any patient with functional instability or pivoting of the knee is considered to have an ACL insufficiency.

ANATOMY
- To fully understand the principles of ACL reconstruction, it is important to understand the complex anatomy of the ACL, which is composed of two major bundles.
  - These bundles are named relative to their relation to the tibial footprint: the posterolateral (PL) bundle is posterior and lateral on the tibial footprint, whereas the anteromedial (AM) bundle is anterior and medial on the tibial footprint.
  - The PL bundle originates more distally and anteriorly relative to the AM bundle on the wall of the intercondylar notch.
  - The femoral insertion site of ACL changes based on flexion angle (FIG 1).
    - With the knee in full extension, the alignment of the AM and PL bundle insertion sites on the femur is vertical.
    - With the knee in 90 degrees of flexion, the insertion sites are horizontal, with the PL bundle insertion site anterior to that of the AM bundle.
  - Measurements of individual bundles have found the AM bundle to be, on average, 38.5 mm long and 7.0 mm wide, whereas the PL bundle is 19.7 mm long and 6.4 mm wide.4,5,8
  - When the knee is extended, the PL bundle is under tension and the AM bundle is moderately lax.
  - With knee flexion, the AM bundle tightens and the PL bundle becomes lax.
  - With internal and external rotation of the tibia at 90 degrees of flexion, the PL bundle tightens.

BIOMECHANICAL STUDIES
- ACL single-bundle reconstruction using either patellar tendon or quadrupled hamstring autograft successfully limits anterior tibial translation but provides insufficient control of the combined rotatory load of internal and valgus torque.9
- In a single-bundle ACL reconstruction, rotatory stability was improved with the use of the 2 o’clock or 10 o’clock femoral tunnel position compared with the 1 o’clock or 11 o’clock position. Neither the 10 o’clock nor the 11 o’clock tunnel position could restore the kinematics and the in situ forces of the intact knee, however.6

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history of a noncontact valgus pivoting injury followed by an effusion of the knee is highly suspicious for an ACL tear.
- The physical examination and methods for examination of the ACL are covered in Chapter SM-41.

- Patients with a partial or single-bundle tear may have either a positive pivot shift or positive Lachman test. For example, an intact AM bundle and torn PL bundle may have a normal Lachman and positive pivot shift, whereas an intact PL bundle and a torn AM bundle may have a normal pivot shift and an increased Lachman test.

IMAGING AND DIAGNOSTIC STUDIES
- Radiographs should include the following views:
  - 30-degree flexion weight-bearing posteroanterior view
  - Lateral
  - Sunrise view of the patella
  - Long-leg alignment view in the case of coronal angular deformity

FIG 1 • Anatomy of the anterior cruciate ligament (ACL). The femoral insertion of the anteromedial (AM) and posterolateral (PL) bundles varies based on degree of flexion. At 0 degrees, the femoral insertion is vertical, with the AM bundle superior to the PL bundle (A), whereas at 90 degrees, the femoral insertion is horizontal, with the PL bundle anterior to the AM bundle (B).
■ MRI should be used to confirm the suspicion of an ACL tear and look for associated injuries of the chondral surfaces (including bone bruises), meniscus, patella, and other ligamentous structures.
■ A KT-1000 arthrometer test is performed to determine absolute translation and side-to-side translation difference.

DIFFERENTIAL DIAGNOSIS
■ Meniscal tear
■ Osteochondral injury
■ Contusion
■ Patellar dislocation
■ Other ligament/capsular injury (eg, medial collateral ligament, lateral collateral ligament, posterolateral corner, multiple ligament injury)
■ It is important to remember that patella dislocation may mimic the initial presentation of ACL tear.

NONOPERATIVE TREATMENT
■ Potential nonoperative candidates and rehabilitation protocol are detailed in Chapter SM-41.

SURGICAL TREATMENT
Indications
■ The indications for anatomic double-bundle ACL reconstruction are similar to those for traditional single-bundle reconstruction.
■ Patients with recurrent instability or episodes of giving way or those who are unable to return to activities of daily living or sports are appropriate for surgical reconstruction.
■ Patients with complaints of instability and a single-bundle or “partial” tear may benefit from single-bundle augmentation, or double-bundle reconstruction in the event the remaining bundle is incompetent.
■ Double-bundle reconstruction has been useful in the revision setting, particularly when the previous femoral tunnel placement was in the traditional “over the top” position, which is too high in the femoral notch. This allows anatomic placement of the two femoral tunnels without interfering with the previous tunnel.

Contraindications
■ We have not found any contraindication to this procedure in the skeletally mature patient.
■ Neither the height of the patient nor the size of the knee has been a factor when performing the surgery.

Evaluation Under Anesthesia
■ Range of motion in comparison to the contralateral knee
■ Ligamentous examination
  ▪ Lachman
  ▪ Pivot shift
  ▪ Varus and valgus stress
  ▪ Anterior and posterior drawer

Positioning
■ The patient is positioned supine on the operating table, and the nonoperative leg is placed in a well-leg holder in the abducted lithotomy position.

A pneumatic tourniquet is applied around the upper thigh of the operative leg, the operative limb is exsanguinated by elevation for 3 minutes, and the tourniquet is insufflated to 300 to 350 mm Hg, depending on patient size.
■ The operative leg is positioned in an arthroscopic leg holder and prepared and draped.

Approach
■ The portals used for this procedure are slightly different from standard arthroscopy portals (FIG 2).
■ The anterolateral portal is placed more superior, at the level of the inferior pole of the patella, just lateral to the patella tendon.
■ A central anteromedial portal is placed just below the inferior pole of the patella, approximately 1 cm lateral to the medial edge of the patella tendon (intratendinous central portal).
■ An accessory anteromedial portal is established using direct visualization with an 18-gauge spinal needle, which is inserted medially and distally to the inferomedial portal, just above the anterior medial meniscus.
■ The accessory medial portal is used for better access to the lateral wall of the intercondylar notch when placing the femoral PL tunnel and femoral AM tunnel if transtibial tunnel location placement is unacceptable.
■ The arthroscope is placed in the central anteromedial portal during femoral tunnel placement for better visualization of the intercondylar notch.
■ The arthroscope is placed in the anterolateral portal for tibial tunnel placement.

![FIG 2 • Portal placement for anatomic double-bundle ACL reconstruction.](image-url)
DIAGNOSTIC ARTHROSCOPY

- Thorough inspection of the joint, including:
  - Patellofemoral joint compartment
  - Lateral compartment and meniscus
  - Medial compartment and meniscus
  - Posterior cruciate ligament
  - ACL
- Any associated meniscal or chondral lesions are addressed before the ACL reconstruction.
- The torn ACL is dissected carefully using a thermal device to determine the injury pattern and with special attention to the anatomic footprints of the two ACL bundles, on the lateral wall of the intercondylar notch and on the tibial insertion (TECH FIG 1).
- Injury patterns may include the following:
  - Tear or stretch of one or both bundles
  - Injury from femoral insertion, tibial insertion, and midsubstance

There are 25 different injury patterns.
- Anatomic insertion sites of the AM and PL bundles on the tibia and femur are marked.
- The tibial footprints are left intact because of their proprioceptive and vascular contributions.

POSTEROLATERAL FEMORAL TUNNEL

- The PL femoral tunnel is the first tunnel to be drilled.
- A 3/32 Steinmann pin is inserted through the accessory anteromedial portal.
- The tip of the guidewire is placed on the femoral footprint of the PL bundle on the lateral wall of the intercondylar notch adjacent to the articular surface (TECH FIG 2A).
- Once the tip of the guidewire is placed in the correct anatomic position (8 mm from anterior and 5 mm from distal articular cartilage), the knee is flexed to 120 degrees and the guidewire is manually tapped into the femur.
- Hyperflexion is performed while placing the PL femoral tunnel to avoid injury to the peroneal nerve when passing a Beath pin.

The guidewire is over-drilled with a 7-mm acorn drill, taking care to avoid injury to the medial femoral condyle articular cartilage.
- The PL tunnel is drilled to a depth of 25 to 30 mm (TECH FIG 2B).
- The far cortex is then breached with a 4.5-mm EndoButton drill (Smith & Nephew, Andover, MA), and the depth gauge is used to measure the distance to the far cortex.

**TECH FIG 1** • Dissection and marking of the femoral insertion of the ACL with a thermal device.

**TECH FIG 2** • A. Insertion of a guide pin in the femoral insertion of the PL bundle through the accessory anteromedial portal. B. PL femoral tunnel drilled to 7 mm diameter.
TIBIAL TUNNELS

- To establish the two tibial tunnels, a 4-cm skin incision is made over the anteromedial surface of the tibia at the level of the tibial tubercle.
- First the PL tunnel is drilled.
- An Accufex (Smith & Nephew, Andover, MA) ACL tibial tunnel tip drill guide set to 55 degrees is placed through the accessory medial portal intra-articularly on the tibial footprint of the PL bundle, which was previously marked using a thermal device (TECH FIG 3A).
- On the tibial cortex, the tibial drill starts just anterior to the superficial medial collateral ligament fibers.
- A 3.2-mm guidewire is then passed into the stump of the PL tibial footprint.

- The AM tibial tunnel is drilled with the tibial drill guide set at 45 degrees and placed through the anteromedial portal, and the tip of the drill guide is placed on the tibial footprint of the AM tunnel (TECH FIG 3B).
- The starting point of the AM tunnel on the tibial cortex is more anterior, central, and proximal than the starting point of the PL tunnel.
- The 3.2-mm guidewire is passed into the stump of the AM tibial footprint, and placement of both guidewires is assessed for satisfactory position (TECH FIG 3C).
- The tibial tunnels are then overdrilled with 7- and 8-mm compaction drill reamers for the PL and AM tunnels, respectively.

ANTEROMEDIAL FEMORAL TUNNEL

- The femoral AM tunnel is the last tunnel to be drilled.
- A transtibial technique is used most commonly, in a similar fashion to that of a femoral tunnel for ACL single-bundle reconstruction (TECH FIG 4A).
- A guidewire is passed through the AM tibial tunnel, and the tip of the guidewire is placed on the femoral footprint of the AM bundle, which was marked previously with a thermal device.
  - At 90 degrees, the location is directly posterior to the PL femoral tunnel.
- If the location of the guidewire tip is unacceptable, the accessory medial portal is used to insert the guidewire in the proper location.
- After the guidewire is inserted in the desired position, an 8-mm acorn drill is inserted over the guidewire, and the AM femoral tunnel is drilled to a depth of 35 mm to 40 mm (TECH FIG 4B).
- The far cortex of the AM femoral tunnel is breached with a 4.5-mm EndoButton drill, and the depth gauge is used to measure the distance to the far cortex.
GRAFT CHOICE

- During the arthroscopic procedure, the ACL grafts are prepared on the back table.
- We prefer to use two separate tibialis anterior or tibialis posterior tendon allografts.
- These grafts usually are 24 cm to 30 cm in length, and we fold each tendon graft to obtain 12- to 15-cm double-stranded grafts (TECH FIG 5).
- The AM tendon double-stranded graft typically is 8 mm, and the PL double-stranded graft is 7 mm.
- Alternatively, autogenous semitendinosus and gracilus grafts can be harvested (see Chap. SM-41) and used for the reconstruction.
- The ends of the tendon grafts are sutured using a whip-stitch with no. 2 Ticron sutures (Tyco, Waltham, MA).

GRAFT PASSAGE

- The PL bundle graft is passed first. A Beath pin with a long looped suture attached to the eyelet is passed through the accessory anteromedial portal and out the PL femoral tunnel and lateral aspect of the thigh.
- Hyperflexion of the knee is performed to protect the peroneal nerve.
- The looped suture is visualized within the joint and retrieved with an arthroscopic suture grasper through the PL tibial tunnel.
- The graft is passed, and the EndoButton is flipped in standard fashion to establish femoral fixation of the PL bundle graft (TECH FIG 6A).
- Next, the AM bundle graft is passed using the transtibial technique and out the anterolateral thigh with a Beath pin loaded with a looped suture (TECH FIG 6B).
- If the transtibial technique is not used for the AM femoral tunnel, then the graft is passed in a similar fashion to the PL bundle graft.
- The EndoButton is flipped in standard fashion to establish femoral fixation of the AM bundle graft.
- Preconditioning of the grafts is performed by flexing and extending the knee through a range of motion (ROM) from 0 to 120 degrees approximately 20 to 30 times.

TECH FIG 6 • A. Arthroscopic view from the anterolateral portal of the passage of the PL bundle graft. The PL graft is passed first, followed by the AM graft. B. Arthroscopic view from the central anteromedial portal following passage of the AM and PL grafts, completing the anatomic double-bundle ACL reconstruction.

FIXATION

- Each graft is looped around an EndoButton.
- The length of the EndoButton loop is chosen according to the measured length of the femoral tunnels.
- On the tibial side, we prefer the use of a bioabsorbable interference screw fixation combined with Richards staple fixation (Smith & Nephew Richards, Memphis, TN) for each graft (TECH FIG 7).
- The PL bundle graft is tensioned and fixed at full extension, and the AM bundle graft is tensioned and fixed at 60 degrees of flexion.
- After the fixation is complete, the knee is tested for stability and full ROM. The wounds are closed in standard fashion, and the leg locked in full extension in a hinged knee brace with a Cryocuff (Aircast, Summit, NJ) placed under the brace.
TECH FIG 7 • Postoperative AP radiograph after anatomic double-bundle ACL reconstruction. The femoral fixation uses an EndoButton for each graft, and tibial fixation is obtained using a bioabsorbable interference screw and Richards staple for each graft.

PEARLS AND PITFALLS

Grafts
- We prefer soft tissue grafts (and prefer allograft over autograft).
- AM graft: 7 to 8 mm
- PL graft: 6 to 7 mm

Examination of injury pattern
- Inspection for tear or stretch of either or both bundles

Portals
- Three portals are used.
- The lateral wall is visualized through the central portal.

Tunnel placement
- Marking anatomic insertion sites
- PL femoral tunnel placed first
- AM femoral tunnel based on PL tunnel

Fixation
- For femur: EndoButton
- For tibia: biointerference screw plus staple

Postoperatively
- Early ROM

POSTOPERATIVE CARE
- The authors’ postoperative rehabilitation follows the same standard protocol used for patients undergoing ACL single-bundle reconstruction using soft tissue grafts.
- Patients wear a hinged knee brace for 6 weeks.
- For the first week, the brace is locked in extension.
- Continuous passive motion is started immediately after surgery, from 0 to 45 degrees of flexion, and is increased by 10 degrees per day.
- Patients use crutches for 4 weeks postoperatively.
- From the first postoperative day, patients are allowed full weight bearing as tolerated.
- Non-cutting and non-twisting sports such as swimming, biking, and running in a straight line are allowed at 12 weeks after surgery.
- Return to full activity level usually is allowed at 6 months postoperatively.

OUTCOMES
- No current long-term studies on the results of anatomic double-bundle ACL reconstruction have been performed.
- Several short-term studies and multiple prospective studies currently are ongoing in Japan, France, Italy, and the United States.
- Muneta et al\textsuperscript{7} reported on 54 patients 2 years after double-bundle ACL reconstruction using autogenous hamstring and found a trend toward improved anterior stability compared with the single-bundle technique.
- Zaricznyj\textsuperscript{11} found 86% good or excellent results at 3.6 years follow-up in 14 patients after using doubled hamstring autograft for ACL reconstruction with one femoral and two tibial tunnels. Rotational stability was achieved in each patient, as demonstrated by a negative pivot shift.
- In a case series with 57 consecutive patients, Yasuda et al\textsuperscript{10} demonstrated that anatomic ACL double-bundle reconstruction
appears to be a safe technique with satisfactory outcomes. They evaluated functional outcomes at 24 to 36 months follow-up and compared their results with historic data on ACL single-bundle reconstruction. Patients undergoing anatomic ACL double-bundle reconstruction trended toward better AP knee stability, as measured by the KT-2000, compared with the single-bundle group.

- In a prospective, randomized clinical trial including 108 patients, Adachi et al compared the outcomes of anatomic ACL double-bundle reconstruction with the ACL single-bundle technique at an average follow up of 32 months. Their outcome measures included AP knee stability, as measured by the KT-2000, and the joint position sense of the knee. These authors did not find any difference between the ACL double-bundle and the ACL single-bundle group.

COMPlications

- Traditional complications for single-bundle reconstruction include graft failure, hardware complications, and infection.
- In our series, we have had three graft failures, all occurring after returning to sports.
  - Two failures were sustained during contact injuries while playing collegiate football. The third occurred in a noncompliant patient 3 months after reconstruction when she returned to playing high school basketball without a brace.
  - Four patients have undergone staple removal for symptomatic hardware.
- Specific complications for double-bundle reconstruction include:
  - Risk of femoral condyle fracture
  - Graft impingement
  - Incorrect tunnel placement
  - Tunnel enlargement
  - Difficulty with revision surgery
- We have performed 186 double-bundle ACL reconstructions and have had no fractures and no radiographic signs of femoral condylar avascular necrosis or tunnel widening.
- Bell et al performed biomechanical and computer modeling studies comparing single and double femoral tunnels and the risk of femoral condyle fracture.
- Results of these studies have shown that fracture risk increased significantly for the single tunnel versus the native condyle procedure, but no significant increase in fracture risk was found for one versus two tunnels.

- ROM studies are in progress. Preliminary results have shown earlier return to full extension and symmetric flexion to the contralateral knee by 3 months after surgery.
- Proper tunnel location is achieved by marking the anatomic sites for each bundle prior to ACL debridement.
- Prospective studies measuring for radiographic tunnel enlargement are ongoing. Thus far, no significant tunnel enlargement has been found; however, follow-up has been short-term only.
- Revision surgery has not been compromised in the two patients in our cohort who have undergone repeat ACL surgery following traumatic re-tear after double-bundle reconstruction.

REFERENCES

DEFINITION

- The anterior cruciate ligament (ACL) is the primary stabilizer preventing anterior displacement of the tibia. The ligament is made up of an anteromedial and a posterolateral bundle.
- The ACL also plays a role in assisting the capsular structures, collateral ligaments, joint surface, and meniscal geometry in preventing rotational instability.
- Failure of a primary ACL reconstruction may be due to traumatic re-rupture, stretch-out of the graft, failure to diagnose concomitant injuries (ie, posterolateral corner injury), or technical issues encountered during primary ACL reconstruction (ie, tunnel malposition, fixation failure etc. See Chap. SM-41).

PATHOGENESIS

- Poor outcomes following ACL reconstruction can be due to a multitude of factors and commonly are grouped into one of four areas: recurrent instability; motion loss; persistent pain; or extensor mechanism dysfunction. This chapter focuses on recurrent instability.
- The incidence of recurrent instability after primary ACL reconstruction is 3% to 10%.9
- Graft failure has been reported as the primary cause of recurrent instability. Three different categories of graft failure have been described: failure of graft incorporation; suboptimal surgical technique (eg, tunnel malposition, loss of fixation); and traumatic re-rupture. Although these categories may occur together, a critical step in the successful outcome of treatment for a failed ACL reconstruction is to define the primary cause of failure.

NATURAL HISTORY

- The natural history of the ACL-deficient knee is not well understood.
- It is commonly thought that patients who continue to experience episodes of instability place the knee at risk of further damage to the articular cartilage and menisci.
- While it may be possible for some patients to avoid activities that result in instability, others may continue to participate in sports, and still others may experience episodes of instability with activities of daily living.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history of the primary injury and reconstruction, postoperative course, ability to return to activity, and current symptoms is helpful to determine the optimal treatment.
- It also is helpful to know the time from the initial injury to the index reconstruction.
- An explanation of the postoperative therapy program and progress should be obtained, and any traumatic episodes after surgery should be noted.
- A copy of the operative report from the previous repair should be obtained from the primary surgeon to note graft type, tunnel placement, fixation methods and materials, and condition of the articular surfaces and menisci at the time of that procedure.
- An antalgic gait may suggest persistent pain after surgery, or a recent second traumatic event.
- A varus thrust during gait is highly suggestive of incompetence of the lateral or posterolateral structures and requires further evaluation with long-film standing anteroposterior radiographs for mechanical alignment.
- Buckling of the knee, especially in the initial phase of gait, may suggest quadriceps weakness, and may give the patient the subjective sensation of knee instability.
- Sensory status and palpation of pulses must be noted in all cases. Any decreases may suggest an initial dislocation of the knee and require appropriate workup to rule out a vascular injury.
- Common examinations to determine instability patterns of the knee include:
  - Anterior drawer test. When compared to the contralateral knee, increased anterior laxity may indicate an ACL-deficient knee.
  - Posterior drawer test. When compared to the contralateral knee, increased posterior laxity may be indicative of a posterior cruciate ligament (PCL)-deficient knee.
- **Lachman’s test.** Sensitive test for ACL deficiency, especially when the contralateral knee has intact native ACL.
- **Varus/valgus stress testing.** Opening in 30 degrees of flexion is consistent with injury to collateral ligaments alone. If opening in both 0 and 30 degrees, injury to collateral ligaments and other structures, such as the cruciate ligaments or capsule, is suggested.
- **Pivot shift.** Highly sensitive test for the ACL-deficient knee. It often is difficult for the patient to relax in the setting of a painful knee, however.
- **Posterolateral drawer test.** Increased posterolateral translation compared with the intact, contralateral knee may suggest posterolateral rotatory instability.
- **Dial test.** Difference of more than 10 degrees at 30 degrees flexion is consistent with injury to the posterolateral corner (PLC). Difference of more than 10 degrees at 90 degrees flexion is consistent with injury to both PLC and PCL.
- **The varus recurvatum test reveals varus angulation, hyperextension, and external rotation of the tibia.** It suggests posterolateral rotatory instability of the knee.
- **Testing for concurrent intra-articular injuries should be performed to detect possible meniscal, articular cartilage, or patellofemoral pathology.**
- **Large effusions are common in the setting of a ruptured native ACL.** In the revision setting, rupture of the graft may not lead to a large hemarthrosis, because of decreased vascularity of the graft material compared to the native ACL. Effusions in the setting of a failed ACL reconstruction may be small or even nonexistent.

### IMAGING AND OTHER DIAGNOSTIC STUDIES
- **Routine radiographs,** including weight-bearing anteroposterior and lateral views as well as patellar views, should be performed. In the revision setting, these images allow for critical assessment of previous tunnel placement and assessment for possible bone loss at previous tunnels, which may require further evaluation and treatment.
- **Metallic fixation devices make previous tunnel placement easy to identify, but bioabsorbable screws and other types of fixation also can be evaluated for tunnel placement on these images (FIG 1).**
- **These images also allow evaluation for possible evidence of osteoarthritis.**
- **If concern regarding a significant amount of bone loss is present after initial radiographic evaluation, CT imaging allows more precise evaluation of possible tunnel enlargement.** MRI also may allow evaluation of tunnel size, along with further evaluation of possible intra-articular pathology.
- **Metallic fixation devices may create significant artifacts on both of these imaging techniques, at times limiting their usefulness.**

**FIG 1 • A,B.** Anterior cruciate ligament (ACL) reconstruction performed with an EndoButton (Smith & Nephew, Andover, MA) on the femur and staple fixation of the graft on the tibia. **C,D.** Anterior placement of the femoral tunnel in this primary ACL reconstruction performed with a two-incision technique.
For varus alignment, or chronic posterolateral rotatory instability, radiographs that allow full evaluation of mechanical alignment may be necessary. These will help the surgeon to determine whether there is a significant varus alignment of the knee.

- In ACL-deficient knees with varus bony alignment, any reconstruction may be doomed to failure if the alignment is not first addressed with an osteotomy procedure.
- Bone scan and serologic tests, including complete blood count, erythrocyte sedimentation rate, C-reactive protein, and bacterial cultures of knee aspirates, should be performed in any setting suggestive of infection, including those cases with significant osteolysis of previous tunnels.

DIFFERENTIAL DIAGNOSIS

- Meniscal injury
- Osteochondral injury
- Subjective weakness or anterior knee pain secondary to quadriceps weakness
- Patella subluxation or dislocation
- Multiligamentous injury (eg, PCL, PLC, medial collateral ligament, lateral collateral ligament)

NONOPERATIVE MANAGEMENT

- Patients with painful ACL-deficient knees after attempted reconstruction must understand that reconstruction of the ACL will not address their pain symptoms and that nonoperative management might be a better approach to address their complaints.
- The basis of any nonoperative treatment for an ACL-deficient knee is to avoid those activities that put the knee at risk, such as cutting sports.
- Strengthening the dynamic stabilizers of the knee, such as the hamstrings (an antagonist to anterior translation of the tibia) may increase stability of the knee for routine activities.
- Bracing

SURGICAL MANAGEMENT

- The primary indication for revision ACL surgery is a patient whose chief complaint is symptomatic instability with his or her activities.
  - ACL reconstruction does not address the pain symptoms of an ACL-deficient knee, and other intra-articular pathology should be investigated as the cause of the subjective pain complaints.
  - ACL reconstruction may decrease the progression of intra-articular pathology, but will not, in itself, treat other lesions that may be present.

Preoperative Planning

- A common cause of failure related to surgical technique is anterior placement of a femoral tunnel, which often is detected on the lateral radiograph ([FIG 1D]). This may lead to tightening of the graft with knee flexion resulting in graft stretch-out or failure.
- A preoperative plan should include evaluation of the knee based on history, examination, and imaging for possible other intra-articular pathology, such as meniscal tears or cartilage lesions. The surgeon should be prepared to address these comorbidities at the time of revision surgery.
- Even if the surgeon does not expect to discover such findings, the possibility of their existence, and their treatment options, must be covered in all preoperative discussions with the patient.

- In the setting of possible posterolateral rotational instability, varus malignment, or significant bone loss requiring bone grafting, the patient must be aware of the possible need for staged procedures, and the necessary postoperative course should this become the case.
- The possibility of hardware removal requires knowledge of any previous implants used, and extraction tools, such as a commercially available ACL revision tray. These should be available in the operating room at the time of surgery.
- Once anesthesia has been induced, a thorough examination of the knee as compared to the contralateral extremity is critical. Concerns regarding posterolateral or varus and valgus instability will not be answered during arthroscopic evaluation and are best assessed prior to prepping and draping.

Positioning

- Our preferred positioning for ACL reconstructive surgery is with the patient in the supine position using a lateral post.
- The lateral post should be placed proximal enough to allow for the surgeon’s hand to drill the tibial tunnel without hitting the table when the patient’s knee is flexed over the edge of the table ([FIG 2]).

Approach

- A standard superolateral outflow and anteromedial and anterolateral portals are used for diagnostic arthroscopy.
  - If the previous incisions were adequately positioned, they may be used, but the placement of portal incisions should not be compromised for the sole purpose of reusing the previous incisions.
  - A complete diagnostic arthroscopic evaluation of the knee should be performed.
  - Treatment of other comorbid conditions should be performed before the ACL reconstruction is done. These include repair or débridement of meniscal tears, removal of loose bodies, débridement with possible microfracture of osteochondral lesions, and hardware removal, if necessary.

![FIG 2 - The lateral post is placed high against the lateral femur to allow adequate room on the medial aspect of the tibia to drill a tibial tunnel without interference from the operative table.](image-url)
The ACL-deficient knee is diagnosed at the time of examination under anesthesia.

After completion of the arthroscopic inspection of the knee and treatment of any other intra-articular pathology, the tourniquet is inflated.

The knee is flexed 90 degrees over a bump under the distal thigh, with the popliteal space free, allowing the neurovascular structures to fall posterior to the posterior capsule of the knee and thus remain out of harm’s way.

The previous graft is removed with a 5.5-mm shaver down to the footprint of the native ACL.

The shaver also is used to remove any fat pad obstructing the view, periosteum off the lateral wall of the notch, and any scar tissue present in the notch.

In revision ACL reconstruction, the notch often is overgrown and narrow, likely as a result of the previous ACL reconstruction (TECH FIG 1A).

A notchplasty is completed with use of a 5.5-mm burr, starting at the anterior opening of the notch if necessary.

The location of the previous femoral tunnel is noted.

Notchplasty is carried back to the posterior wall as needed. A small, curved curette may be used to inspect the back of the notch. A thin white strip of periosteum usually identifies the posterior wall (TECH FIG 1B). Careful attention to localizing the posterior wall is critical, especially because the sides and roof of the notch often are irregular owing to the previous surgery.

Anterior placement of the femoral tunnel is the primary cause of recurrent laxity for ACL reconstructions, so in many cases there is enough room to place a second femoral tunnel in the appropriate position without interference or compromise from the previous tunnel. If this is the case, the previous interference screw can be left in place or removed (TECH FIG 1C,D).

A curved curette is used to remove a small area of bone to localize the desired position of the new femoral tunnel.

A more difficult scenario is the situation where the femoral tunnel was well placed. In this case, it can be difficult to create a new tunnel that does not overlap with the old tunnel.

We have found that transtibially placed femoral tunnels often can be revised by drilling the revision tunnel through the anteromedial portal. In this way, the tunnels diverge, with only the intra-articular outlets overlapping (TECH FIG 1E).

Likewise, if a previously well-placed femoral tunnel was placed via the anteromedial portal, it often can be revised by drilling transtibially.

**TECH FIG 1** - A. Significant overgrowth of the notch noted at the time of revision anterior cruciate ligament (ACL) reconstruction. B. A thin layer of periosteum is easily visualized at the posterior wall of the notch. C. Note the anterior placement of the femoral tunnel interference screw used during the primary ACL reconstruction. The femoral tunnel for the revision can be placed at the appropriate location without removing the interference screw used in the primary procedure. D. The new femoral tunnel and interference screw are placed in the appropriate location without compromise from the screw used in the index procedure. E. View of femoral notch after placement of femoral tunnel and interference screw via anteromedial portal. This allows divergence of the old and new femoral tunnels.
**GRAFT PREPARATION**

- We usually wait to prepare the graft until the tunnels are drilled. This way the bone plugs on the graft can be oversized, in the unlikely event that the new tunnel and old tunnel substantially overlap and create a bony defect that is considerably larger than the standard tunnel size.
- The graft of choice can be used.
  - We do not reharvest previously harvested tendons.
  - Graft options include both autogenous and allogenic grafts.
  - We commonly use bone–patellar tendon–bone allograft.
- Both bone plugs are cut to a length of 25 mm, with a height of 10 mm and width of 10 mm using a micro oscillating saw.
- A small rongeur is used to contour the bone plugs to fit through a 10-mm tunnel.
- A 2-mm drill is used to drill one hole between the proximal two thirds and the distal one third of the bone plug from the patella.
- Two similar holes are drilled in the tibial bone plug at one- and two-thirds the length of the plug, at a 90-degree angle to each other.
- No. 5 Ethibond (Ethicon, Inc.) sutures, loaded on Keith needles, are then passed through each hole.
- The graft is then passed through a 10-mm sizer. The graft should slide easily while still having contact with the sides of the sizer.
- The length of the tendon part of the graft is then measured from bone plug to bone plug.
- The graft is wrapped in saline-soaked gauze and protected on the back table.

**TUNNEL PLACEMENT**

- Neither tibial nor femoral tunnel placement should be compromised based on the location of the previous tunnels.
- The tibial tunnel guidewire is placed the same as for a primary ACL reconstruction, using a commercially available tibial guide.
  - We set the tibial guide at \( n + 7 \), with \( n \) being the length of the graft between the two bone plugs (\( n + 7 \) rule).\(^8\)
  - The tip of the guide is placed in the posteromedial aspect of the native ACL footprint. The difficulty is that the native ACL footprint is no longer visible. Therefore, we place the guidewire so that it penetrates the joint 6 to 7 mm anterior to the PCL and in a line that intersects the posterior aspect of the anterior horn insertion of the lateral meniscus (TECH FIG 2A).
- The guide is placed in the joint through the anteromedial portal, and a 1.5-cm skin incision is placed just medial to the tibial tubercle, in line with the anteromedial portal for placement of the guidewire.
- If a metallic tibial interference screw was used in the previous reconstruction, it usually is in a location that necessitates its removal.
  - At this point the leg is brought back onto the table, and the interference screw is localized.
  - All overgrown soft tissue and bone is carefully removed, and then the appropriate driver (based on the operative note from the previous procedure) is placed into the head of the screw and it is removed.
  - Next, the guide is rechecked, with the sliding bullet placed down to bone. The measurement on the bullet should be just longer than the tendinous portion of the graft (\( n + 2 \) rule).\(^11\)

**TECH FIG 2** • A. Placement of the tibial tunnel guidewire just anterior to the native posterior cruciate ligament (PCL). B. Appearance of the revision tibial tunnel using the arthroscope to inspect for compromise from the index procedure. C. After reaming the femoral tunnel to a depth of 10 mm, the tunnel is inspected to ensure the posterior wall is intact.
The guidewire is then advanced, and, if correctly placed, the tibial tunnel is made with a 10-mm drill.

The tunnel is inspected with the arthroscope for wall compromise from the previous tunnel (TECH FIG 2B). This can be performed by placing the arthroscope up the tibial tunnel.

If there is concern for fixation strength with the interference screw, the tibial bone plug can be reinforced by tying the suture previously placed through the bone plug over a post just distal to the tibial tunnel.

Attention is then directed to the femoral notch.

A point is marked with a curette in the femoral notch 6 mm (for a 10-mm graft) anterior to the posterior wall in the 1:00 to 1:30 position (left knee) or the 10:30 to 11:00 position (right knee).

A Beath pin is advanced across the joint to the previously marked site on the femur. This usually can be done transtibially.

In some cases, it is not possible to get the pin to the desired location. In such a case, the knee is flexed to 120 degrees and the Beath pin is passed through the anteromedial portal.

As previously mentioned, this technique also can be used when the previous femoral tunnel was placed in an acceptable position transtibially.

This allows for divergence of the new tunnel with respect to the old without compromising the entry point into the femoral notch.

A 10-mm acorn reamer is then advanced by hand through the joint, using care not to damage the PCL.

The reamer is advanced to a depth of 10 mm.

It is then brought back into the notch so that the back wall can be inspected (TECH FIG 2C).

At this time, the tunnel also is inspected to ensure that the previous femoral tunnel does not compromise the new tunnel.

If there is compromise, one of the other techniques mentioned in the following sections is performed.

If the back wall is intact, the reamer is advanced to a depth of 30 mm.

GRAFT PASSAGE AND TENSIONING

Once appropriate tunnels have been drilled, the single suture from the bone plug from one end of the graft is passed through the Beath pin and then advanced into place.

The bone plug is advanced into the femoral tunnel under careful visualization to ensure the graft does not rotate and the bone plug is in the anterior aspect of the tunnel.

The knee is flexed to 120 degrees, and the interference screw is placed while gentle tension is maintained on the graft.

Again, careful visualization is used to ensure the graft is not cut by the threads of the advancing screw.

The screw is advanced so that it is recessed 1 to 2 mm from the tunnel opening (TECH FIG 3).

After checking for appropriate isometry of the graft by palpating the tibial bone plug through an arc of motion, the graft is manually tensioned.

While maintaining tension, the knee is flexed to about 10 to 20 degrees, and the tibial interference screw is placed.

TECH FIG 3 • The femoral interference screw is seated approximately 1 to 2 mm beyond the opening into the notch.

A final range-of-motion check is performed, and a gentle Lachman test is performed to ensure that stability has been restored.

TWO-INCISION TECHNIQUE

In cases in which the previous femoral tunnel was placed in the location that would have been preferred for the current one, or osteolysis around the previous tunnel makes placement of the new tunnel difficult, the two-incision technique may be used to create the femoral tunnel.

This technique uses the same tunnel aperture, but at a different angle.

This allows for fixation of the femoral bone plug at the lateral cortex of the distal femur, a location typically not affected by previous ACL reconstruction.

In cases in which the primary ACL reconstruction was performed with a two-incision technique, our standard endoscopic technique usually works without difficulty for placement of the femoral tunnel.

After drilling the tibial tunnel, and assessment that the femoral tunnel location necessitates two-incision technique, a commercially available, rear-entry, drill guide is used.

A lateral incision is performed over the distal metaphyseal region.
The tip of the guide is placed at the posterior aspect of the lateral wall of the notch in the 1:30 position (left knee) or 10:30 position (right knee).

- The sliding bullet is advanced to bone, and the guidewire is advanced.
- While protecting the PCL with a large curette, the femoral tunnel is reamed with a 10-mm reamer.
- After graft passage using suture material in the bone plugs of the graft, an interference screw is placed at the lateral cortex and advanced until it is adjacent with the bone plug (TECH FIG 4).
- The remainder of the procedure is performed as previously described.

TECH FIG 4 • The femoral interference screw is placed into the femoral tunnel through the lateral cortex.

BONE GRAFTING OF TIBIAL TUNNELS

- If significant bone loss has occurred around the previous tibial tunnel, bone grafting may be necessary, followed by staged revision ACL reconstruction. This is common with synthetic grafts, which can cause an immune reaction to the graft material, and also has been proposed to occur more frequently with hamstring grafts owing to the theoretical “windshield wiper” effect of the graft with fixation at the distal end of the tunnel.3,13
- After removal of the fixation devices, the previous tunnels are fully débrided of soft tissue using a shaver, curette, and rasp.
- If sclerotic bone is encountered, a 2-mm drill can be used to drill the wall of the tunnel.
- The old tunnels and regions of bony deficiency can be filled with autograft bone (taken in dowels from the iliac crest13), or allograft dowels (commonly available from tissue banks3).
- Allograft dowels, when used, should be about 1 mm larger than the diameter of the tunnel and placed using a press-fit technique.
- Reconstruction must be staged to allow time for incorporation of the bone graft.
- Incorporation of the bone graft can be monitored on CT imaging; it usually takes 4 to 6 months.13

PEARLS AND PITFALLS

| Indications | It is critical to determine whether the patient’s chief complaint is instability or pain.
|             | For patients 25 years of age and younger, a good reason is needed not to perform revision reconstruction of an ACL-deficient knee.
|             | For patients 45 years of age and older, a good reason is needed to consider revision reconstruction in an ACL-deficient knee.
|             | Subjective and objective findings of instability should be present to support consideration of revision surgery. Some patients with objective instability are able to participate at a high level of competition in cutting sports without symptomatic instability.
| Interference screws | In our experience, metallic screws allow easy identification of tunnel placement. We currently do not use “bioabsorbable” screws because we have found that they commonly do not absorb and can be difficult to drill across and difficult to remove during revision surgery.
| Synthetic grafts | Careful débridement of all synthetic material must be performed to prevent further immune reaction around the new graft.

POSTOPERATIVE CARE

- In the operating room the knee is placed in a hinged knee brace locked in extension, and the patient is permitted to bear weight as tolerated with the brace.
- At all other times, the brace can be removed and immediate postoperative range of motion is begun.
- Once adequate quadriceps control has been regained, the hinged knee brace is discontinued.
OUTCOMES

The critical factor in successful revision ACL reconstruction is to determine why the initial ACL reconstruction failed before planning the revision surgery. The ultimate clinical outcome likely is based on a combination of factors, including laxity, chondral injury, and meniscal status.

Grossman et al., in a study that focused on failure of revision ACL reconstruction based on patholaxity, found fairly similar outcomes for subjective and objective measures when compared with primary ACL reconstruction studies.

However, only 68% of these patients were able to return to the level of activity and sport they had before the initial injury, significantly lower than the commonly reported 75% to 85% return to pre-injury level sports with primary ACL reconstruction.

A prospective study by Noyes and Barber-Westin looking at revision ACL reconstructions using autogenous bone-patellar tendon–bone grafts resulted in an improvement in subjective scores in 88% of patients, with 62% of these patients able to return to athletics without symptoms.

The authors did report an overall graft failure rate of 24%, a threefold increase compared to a previous study by the same authors looking at primary ACL reconstruction.

In both of the studies by Noyes and Barber-Westin, the condition of the articular cartilage had a significant effect on the subjective scores.

In their later study, Noyes and Barber-Westin reported that 93% of patients had compounding problems such as articular cartilage damage, meniscal pathology, loss of secondary ligament restraints, and varus malalignment.

While reconstruction of the ACL may provide stability to the knee, these compounding problems play a significant role in patient satisfaction and in patients’ ability to return to their level of activity before the primary surgery.

COMPLICATIONS

- Loss of motion
- Graft failure
- Anterior knee pain secondary to damage to the patellofemoral cartilage or quadriceps weakness
- Unrealistic expectations in those patients with articular cartilage damage regarding their ability to return to strenuous sports
- Complex regional pain syndrome

REFERENCES

DEFINITION

- The posterior cruciate ligament (PCL) serves as the primary restraint to posterior translation of the tibia relative to the femur.
- PCL injuries are uncommon, may be partial or complete, and rarely occur in isolation.
- Our understanding of the PCL with respect to its natural history, surgical indications and technique, and postoperative rehabilitation is improving rapidly.

ANATOMY

- The PCL has a broad femoral origin in a semicircular pattern on the medial femoral condyle.
  - It inserts on the posterior aspect of the tibia, in a depression between the medial and lateral tibial plateaus, 1.0 to 1.5 cm below the joint line.
  - Its width, on average, is 13 mm, which is variable along its course; the average length is 38 mm.
- Anatomic studies have delineated separate characteristics of the anterolateral (AL) and posteromedial (PM) bundles within the PCL.
  - The AL bundle origin is more anterior on the intercondylar surface of the medial femoral condyle, and the insertion is more lateral on the tibia, relative to the PM bundle.
  - The larger AL bundle has increased tension in flexion, whereas the PM bundle becomes more taut in extension.
- The meniscofemoral ligaments, which arise from the posterior horn of the lateral meniscus and insert on the posterolateral aspect of the medial femoral condyle, also contribute to the overall strength of the PCL.

PATHOGENESIS

- Acutely, there usually is a history of a direct blow to the anterior lower leg. Common mechanisms include high-energy trauma and athletic injuries.
  - In motor vehicle trauma, the “dashboard injury” occurs when the proximal tibia strikes the dashboard, causing a posteriorly directed force to the proximal tibia.
  - Athletic injuries usually involve a direct blow to the anterior tibia or a fall onto a flexed knee with the foot in plantar flexion.
- Hyperextension injuries, which often are combined with varus or valgus forces, often result in combined ligamentous injuries.

NATURAL HISTORY

- There is little conclusive clinical information regarding the natural history of patients with PCL tears treated nonoperatively.
  - Most studies suggest that patients with isolated grade I–II PCL injuries usually have good subjective results, but few achieve good functional results.\(^{11,13,14}\)
- A high incidence of degeneration, primarily involving the medial femoral condyle and patellofemoral joint, has been noted in patients treated nonoperatively. This finding is especially prevalent in those patients with grade III injuries or combined ligamentous injuries.
- Consequently, pain rather than instability may be the patient’s primary symptom following a PCL injury treated nonoperatively.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The initial history should focus on the mechanism of injury, its severity, and associated injuries.
- With acute injuries, the patient often does not report feeling a “pop” or “tear,” as often is described with ACL injuries.
- The history also should focus on assessing the chronicity of the injury and the instability and pain experienced by the patient.
- A complete knee examination, including inspection, palpation, range of motion (ROM) testing, neurovascular examination, and special tests, should be performed.
- Posterior drawer test: the most accurate clinical test for PCL injury
  - Posterior sag (Godfrey) test: A positive result is an abnormal posterior sag of the tibia relative to the femur from the force of gravity. This result suggests PCL insufficiency if it is abnormal compared to the contralateral side.
  - Quadriceps active test: useful in patients with combined instability. A posteriorly subluxed tibia that reduces anteriorly is a positive result.
  - Reverse pivot shift test: A palpable reduction of the tibia occurring at 20 to 30 degrees indicates a positive result. The contralateral knee must be examined, because a positive test may be a normal finding in some patients.
- Dial test: A positive test is indicated by asymmetry in external rotation. Asymmetry of more than 10 degrees at 30 degrees rotation indicates an isolated posterolateral corner (PLC) injury, while asymmetry at 30 and 90 degrees suggests a combined PCL and PLC injury.
- Posterolateral external rotation test: Increased external rotation of the tibia is a positive result. Increased posterior translation and external rotation at 90 degrees indicate a PLC or PCL injury, while subluxation at 30 degrees is consistent with an isolated PLC injury.
- It is important to assess the neurovascular status of the injured limb, especially if there is a history of a knee dislocation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographs of the knee should be performed following an acute injury to assess for a fracture. An avulsion of the tibial insertion of the PCL may be identified on a lateral radiograph (FIG 1A).
In the chronic setting, radiographs may identify posterior tibial subluxation (FIG 1B) or medial and patellofemoral compartmental arthrosis. Stress radiographs may be used to confirm and quantify dynamic posterior tibial subluxation. Long-cassette films should be obtained if coronal malalignment is suspected. MRI is important to confirm a PCL injury, determine its location and completeness, and assess for concomitant injury, including meniscal and PLC pathology.

**DIFFERENTIAL DIAGNOSIS**
- Combined ligament injury
- PLC injury
- ACL tear
- Tibial plateau fracture
- Articular cartilage injury
- Medial or lateral collateral ligament tear
- Meniscal tear
- Patellar or quadriceps tendon rupture
- Patellofemoral dislocation

**NONOPERATIVE MANAGEMENT**
- Most experts advocate nonoperative management of isolated, partial PCL injuries (grades I and II).
  - In these cases, we recommend immobilization in full extension with protected weight bearing for 2 weeks. The goal is to protect the healing PCL/PLC.
  - ROM exercises are advanced as tolerated, and strengthening is focused on the quadriceps muscles.
  - Closed chain exercises (foot on the ground) are recommended.
  - Applying an axial load across the knee causes anterior translation of the tibia because of the sagittal slope. This important biomechanical principle allows early ROM exercises and protects PCL/PLC healing.

  - The patient usually can return to athletic activities after isolated grade I and II PCL injuries in 4 to 6 weeks. It is important to protect the knee from injury during this time to prevent progression to a grade III injury.
  - Functional bracing is of little benefit after return to sports activities.
  - Isolated grade III injuries are more controversial, and nonoperative management may be appropriate in certain patients.
    - We recommend immobilization in full extension for 2 weeks to prevent posterior tibial subluxation. Weight bearing is protected during these 2 weeks, then slowly advanced.
    - Quadriceps strengthening such as quadriceps sets and straight leg raises is encouraged; hamstring loading is prohibited until later in the rehabilitation course.
    - After 1 month, ROM, full weight-bearing, and progression to functional activities are instituted.
    - Return to sports usually is delayed for 2 to 4 months in patients with grade III injuries.

**SURGICAL MANAGEMENT**
- Surgical indications include those patients with displaced bony avulsions, acute grade III injuries with concomitant ligamentous injuries, and chronic grade II–III injuries with symptoms of instability or pain.
  - With any PCL injury, it is imperative to assess the PLC to rule out injury, because surgery is indicated for combined injuries.
  - In higher-level athletes, surgical treatment may be considered for acute isolated grade III PCL injuries.
  - The timing of PCL reconstruction depends on the severity of the injury and the associated, concomitant ligamentous injuries.
  - Displaced bony avulsions and knees with multiligamentous injuries should be addressed within the first 3 weeks to provide the best opportunity for anatomic repair.
  - A number of graft options are available for PCL reconstruction.
    - Autologous tissue options include bone–patellar tendon–bone, hamstring tendons, and quadriceps tendons.
    - Advantages of allograft tissue include decreased surgical time and no harvest site morbidity. Disadvantages include the possibility of disease transmission. The operating surgeon should discuss these issues with the patient preoperatively.
    - Currently, allograft tibialis anterior tendon is our graft of choice for single- and double-bundle PCL reconstructions (FIG 2).

**Preoperative Planning**
- In the office setting, the surgeon should have a variety of options available and explain that the final surgical plan will depend on the examination under anesthesia (EUA) and the diagnostic arthroscopy.
In the preoperative holding area, sciatic and femoral nerve block catheters may be placed by the anesthesiology staff.

- No anesthetic is introduced, however, until neurologic assessment has been completed.
- After anesthesia induction in the operating room, an EUA is performed on both the nonoperative and the operative knees.
- A detailed examination is performed to determine the direction and degree of laxity.
- Data from the contralateral knee may be particularly helpful with combined injuries.
- Fluoroscopy may be used after the EUA to assess posterior tibial displacement.

Positioning

- The patient is positioned supine on the operating room table.
- We do not use a tourniquet.
- Depending on the anticipated length of the planned procedure, a Foley catheter may be used.
- A padded bump is taped to the operating room table to hold the knee flexed to 90 degrees. A side post is placed on the operative side just distal to the greater trochanter to support the proximal leg with the knee in flexion (FIG 3A). Padded cushions are placed under the nonoperative leg.
- For the inlay technique, a gel pad bump is placed under the contralateral hip to facilitate later exposure to the posteromedial knee of the operative extremity in the figure 4 position.
- After prepping and draping the operative site, a hole is cut in the stockinette for access to the dorsalis pedis pulse throughout the case (FIG 3B).

Approach

- Several techniques have been described for PCL reconstruction. We have developed the following treatment algorithm:
  - For acute injuries, we employ the single-bundle technique.
  - If some component of the native PCL remains, we spare this tissue and use the augmentation technique.
  - This technique can be time-consuming and difficult, but preservation of PCL tissue may provide enhanced posterior stability of the knee and may promote graft healing.
  - We most commonly perform the double-bundle technique in the chronic setting, when any remaining structures are significantly incompetent.
  - Some authors advocate the tibial inlay technique for all settings. We typically do not use this technique, but have included a description of an open double-bundle technique here as part of a comprehensive overview. All arthroscopic tibial inlay techniques also have recently been described.6,9
  - In cases of displaced tibial avulsion, we use the technique described in the Techniques box.

SINGLE-BUNDLE TECHNIQUE

Diagnostic Arthroscopy

- A bump is placed between the post and the leg to stabilize the knee in a flexed position while the foot rests on the pre-positioned sandbag.
- The knee is flexed to 90 degrees, and the vertical arthroscopy portals are delineated.
- The anterolateral portal is placed just lateral to the lateral border of the patellar tendon and adjacent to the inferior pole of the patella.
- The anteromedial portal is positioned 1 cm medial to the medial border of the superior aspect of the patellar tendon.
- Diagnostic arthroscopy is conducted to determine the extent of injury and evaluate for other cartilage or meniscal derangements.
- The notch is examined for any remaining intact PCL fibers. If augmentation is to be performed, care should be taken to preserve these fibers (see Single-Bundle Augmentation Technique).
First the 70-degree arthroscope is placed into the anterolateral portal, and a commercially available PCL curette is introduced through the anteromedial portal. A lateral fluoroscopic image can be obtained to confirm its position. The 30-degree arthroscope is then introduced through the posteromedial portal. The soft tissue on the posterior aspect of the tibia is carefully elevated centrally and slightly laterally. A shaver can be placed through the anterolateral portal to débride some of the surrounding synovium. The 70-degree arthroscope is returned to the anterolateral portal and the shaver placed in the posteromedial portal to complete the exposure.

Creating the Tibial Tunnel

A commercially available PCL tibial drill guide set to 55 degrees is advanced through the anteromedial portal and placed just distal and lateral to the PCL insertion site, 1.5 cm distal to the articular edge of the posterior plateau along the sloped face of the posterior tibial fossa (TECH FIG 2A). The position is checked fluoroscopically using a lateral view and arthroscopically via the posteromedial portal. An incision and dissection through periosteum to bone is made on the anteromedial aspect of the tibia in line with the guide. The PCL guide is set, and its position is confirmed with fluoroscopy and arthroscopy (TECH FIG 2B). A guidewire is drilled to but not through the posterior cortex. Fluoroscopy is used to confirm the path of the guidewire (TECH FIG 2C,D). With the 30-degree arthroscope in the posteromedial portal, the PCL curette is introduced through the anteromedial portal and is used to protect the posterior knee.

Preparation and Exposure of the Tibia

Correct preparation and exposure of the tibia is essential for drilling the tunnel safely in the appropriate position.
structures as the guidewire is carefully advanced through the posterior cortex under arthroscopic visualization.

- A parallel pin guide can be used to make small pin placement corrections if necessary.
- A cannulated compaction reamer is used to drill the tibial tunnel.
- The tibial cortex is cautiously perforated by hand reaming under arthroscopic visualization.
- The tunnel is irrigated, and increasing serial dilators are used under arthroscopic visualization up to the graft size.

Creating the Femoral Tunnel

- An angled awl, via the anterolateral portal, is used to create a starting hole at the 1:00 (right knee) or 11:00 (left knee) position.
- The anteroposterior position depends on the size of the graft, but the hole should be positioned so the tunnel edge is located at the junction with the articular cartilage (TECH FIG 3).
- A guidewire is impacted into the starting hole via the anterolateral portal.
- An appropriately sized cannulated acorn reamer is carefully passed over the guidewire, taking into consideration the close proximity of the patellar articular surface.
- The tunnel is drilled to a depth of approximately 30 mm, taking care to avoid penetrating the outer cortex of the medial femoral condyle.
- Increasing serial dilators are passed to match the size of the graft.
- A smaller EndoButton drill (Smith & Nephew, Andover, MA) is used to perforate the outer cortex of the medial femoral condyle, and a guidewire is inserted through the anterolateral portal into the femoral tunnel.
- An incision is made parallel to Langer’s lines over the anteromedial aspect of the distal medial femoral condyle, at the estimated exit of the guidewire from the bone.
- The vastus medialis obliquus fascia and muscle is split in line with their fibers, and the muscle and periosteum are elevated off the anteromedial distal femur.
- The drill hole is exposed and guidewire is removed.

Graft Passage

- Passage of the graft may require enlarging the anterolateral portal.
- The 30-degree arthroscope is placed in the posteromedial portal, and a long 18-gauge bent wire loop is passed with the loop bent upward from anterior and distal to posterior and proximal through the tibial tunnel.
- A tonsil is introduced through the anterolateral portal and through the notch to retrieve the bent wire loop (TECH FIG 4).
- Leading sutures from the free ends (tibial side) of the graft are placed through the wire loop.
- The wire and sutures are pulled back through the tibial tunnel in an anterograde fashion.
- A small scooped malleable retractor is introduced through the anterolateral portal and placed just posterior to the femoral tunnel to retract the fat pad and provide an unobstructed path for a Beath pin.
- A Beath pin is then passed through the anterolateral portal and through the femoral tunnel.
- The lead suture limbs from the EndoLoop (Ethicon, Inc.) side of the graft are threaded through the eye of the Beath pin.
- The pin, with the suture limbs, is pulled proximally.
- Traction on the suture limbs pulls the graft into the femoral tunnel to the marked line, while traction of the tibial suture limbs pulls the graft into the femoral tunnel.
- The position of the graft is confirmed arthroscopically.

Graft Fixation

- Graft fixation is achieved by placing the EndoLoop along the medial femur with a tonsil to estimate its most proximal extent.
- A 3.2-mm drill bit is used to make a unicortical hole at the most proximal extent of the EndoLoop.
- After the hole is measured and tapped, a 6.5-mm cancellous screw and washer are placed through the EndoLoop into the femur.
- The screw is tightened as the graft is pulled tight distally.
- The fixation is palpated to ensure the EndoLoop limbs are tight distal to the screw and washer.
**Wound Closure**
- The incisions are irrigated, and the fascia in the anterolateral femoral incision is closed with size 0 Vicryl suture.
- The subcutaneous layer is approximated with interrupted, inverted 3-0 Vicryl suture, and the skin is closed with a running 4-0 absorbable suture.
- The portals are closed with 3-0 nylon suture.
- The dorsalis pedis and posterior tibialis pulses are assessed by palpation and a Doppler ultrasound examination if necessary.
- The incisions are covered with adaptic gauze and sterile gauze, then wrapped in cast padding and bias wrap.

**SINGLE-BUNDLE AUGMENTATION**
- For single-bundle augmentation, much of the technique is identical to the single-bundle technique already described. Often, the AL bundle is ruptured and the PM bundle remains intact. Consequently, for the purposes of this chapter, AL bundle augmentation will be described.
- The diagnostic arthroscopy is performed.
- If the AL bundle is found to be intact, special care is taken to preserve this bundle while the overlying synovium and ruptured PCL fibers are débrided (TECH FIG 5A).
- When preparing the posterior aspect of the tibia, preservation of the PCL origin is essential.
- Tibial tunnel preparation is performed similarly to the single-bundle technique.
  - The exit point for the guide pin along the sloped face of the posterior tibial fossa is just distal and lateral to the intact PCL insertion site (TECH FIG 5B).

**DOUBLE-BUNDLE RECONSTRUCTION**
- For double-bundle PCL reconstruction, the initial aspects of the technique are identical to those of single-bundle reconstruction, including portal placement, arthroscopy, and preparation for drilling.

**Tibial Tunnel Creation**
- Throughout this process, care must be taken to avoid tunnel convergence and ensure an adequate bony bridge between the two tibial tunnels.
- First, the guide pin for the AL tunnel is positioned using the same technique as with single-bundle reconstruction.
  - It exits the tibia just distal and lateral to the PCL insertion site, 1.5 cm distal to the articular edge of the posterior plateau.
  - The PCL guide is reintroduced into the joint.
- When preparing the medial femoral condyle for tunnel drilling, care again is taken to preserve the intact PCL bundle.
  - The starting hole is placed at the 1:00 (right knee) or 11:00 (left knee) position.
  - The hole should be positioned in the anteroposterior plane so the tunnel edge is located at the junction with the articular cartilage.
  - This location depends on the size of the graft and the distance from the intact PM bundle.
  - The graft is passed around the intact bundle, which is the final augmentation consideration.
  - Fixation and closure are then performed.

**TECH FIG 5**
- **A.** An intact AL bundle is preserved and the overlying synovium and ruptured PCL fibers are débrided. **B.** The exit point for the tibial tunnel along the sloped face of the posterior tibial fossa is just distal and lateral to the intact PCL insertion, as demonstrated by a long 18-gauge bent wire loop.

The same steps and precautions are repeated for placement of the PM tibial guidewire.
- The PM tibial guidewire enters the tibia on the anteromedial aspect of the tibia, slightly more proximal and medial than the AL guidewire.
- Conversely, the PM guidewire can be introduced through the anterolateral tibia, crossing the AL guidewire on the coronal view, but remaining proximal to the AL guidewire throughout its course on the sagittal view. It exits the tibia in the footprint more medial and slightly proximal to the AL tibial guidewire (TECH FIG 6A).
- It is important to ensure adequate separation between the two guide pins to accommodate both tunnels with a bony bridge separation.
Once the guidewire positions are satisfactory, a cannulated compaction reamer is used to first drill the AL tibial tunnel.
- The drill is advanced under fluoroscopic guidance.
- The posterior tibial cortex is cautiously perforated by hand reaming under arthroscopic visualization.
- The tunnel is irrigated, and increasing serial dilators are used under arthroscopic visualization.
- The steps are repeated for drilling the PM tibial tunnel with a 7-mm cannulated compaction reamer (TECH FIG 6B).

**Femoral Tunnel Creation**

- An angled awl is used to create the starting holes.
- For the AL bundle, the starting hole is placed at the 1:00 (right knee) or 11:00 (left knee) position.
- The hole should be positioned in the anteroposterior plane so the tunnel edge is located at the junction with the articular cartilage.
- The guidewire is passed via the anterolateral portal and impacted into the starting hole.
- The appropriately sized cannulated acorn reamer is passed over the guidewire.
- The reamer should be passed carefully, given the close proximity of the patellar articular surface.
- The tunnel is drilled to a depth of about 30 mm, with care taken to avoid penetration of the outer cortex of the medial femoral condyle.
- Increasing serial dilators are passed to match the size of the graft.
- A smaller EndoButton drill (Smith & Nephew, Andover, MA) is used to perforate the outer cortex of the medial femoral condyle.
- This inside-out femoral tunnel preparation technique is then repeated for the PM tunnel.
- The angled awl is used to create the starting hole at the 3:00 (right knee) or 9:00 (left knee) position.
- The PM tunnel is placed parallel or slightly posterior to the AL tunnel.
- The guide pin is then placed via the anterolateral portal and impacted into the starting hole.
- A 7-mm acorn reamer is passed over the guidewire and drilled to a depth of approximately 30 mm (TECH FIG 7).
- The medial femoral condylar cortex is perforated with the EndoButton drill.

**Graft Placement and Fixation**

- The AL graft is passed first, using the same technique as with single-bundle reconstruction.
- This process is then repeated for the PM graft (TECH FIG 8).
- It is helpful to keep tension on the AL graft suture ends when passing the PM graft to ensure that the AL graft does not get pulled into the joint.
- Graft fixation is performed first on the femoral side.
- The AL bundle is secured as previously described.
- This process is repeated for the PM bundle, ensuring that adequate separation exists between the two screws and washers to prevent overlap.
- An anterior tibial force is applied to reduce the tibia before and during final tibial fixation.
- Two 4.5-mm cortical screws and washers are placed from anteromedial to posterolateral within the proximal tibia, just distal to the respective tunnels.
- As with the single-bundle technique, before the screw advances to the second cortex, the suture limbs from the tibial side of the graft are tied with tension over the post, and then the screw is tightened.
- The AL graft is secured first at 90 degrees flexion, and the PM bundle then is secured at 15 degrees of flexion.
- The arthroscope is inserted to confirm adequate position, tension, and fixation of the grafts.
Tibial Inlay

For the double-bundle tibial inlay PCL reconstruction, the initial aspects of the technique are similar to those for single-bundle reconstruction, including portal placement, arthroscopy, and débridement.

A whole, nonirradiated, frozen patellar tendon allograft is prepared with two bundles attached to a common tibial bone block and distinct femoral bone blocks.

- The tibial bone block is fashioned from the tibial side of the graft and should measure 20 mm long, 13 mm wide, and 12 mm thick.
  - A single 4.5-mm gliding hole is placed in the center of the block for later fixation.
- The tendon bundles stemming from the tibial bone block should measure 11 mm (AL bundle) and 9 mm (PM bundle).
- The femoral bone plugs from the patellar side of the graft are shaped to 20 mm in length and 11 mm (AL bundle) and 9 mm (PM bundle) in diameter.
  - The femoral bone plugs are each drilled with two separate 2.0-mm holes, through which Fiberwire (Arthrex, Naples, FL) passing sutures are placed.
- The leg is brought into a figure 4 position, with the knee flexed to 90 degrees and the bump repositioned under the lateral ankle.
  - A 6-cm incision is made over the posterior border of the tibia from the crease of the popliteal fossa and curving distally along the posteromedial border of the tibia.

The dissection is continued through the subcutaneous fat to the sartorius fascia and the fascia overlying the medial head of the gastrocneumius.

- The fascia is incised along the palpable posteromedial tibial border.
- The semimembranosus and pes anserinus tendons are retracted anteriorly and proximally.
- The medial head of the gastrocneumius is elevated from the tibial cortex and retracted posteriorly.
- The medial border of the gastrocneumius is followed distally along the posterior tibia, and the proximal border of the popliteus muscle is identified. The popliteus muscle is elevated subperiosteally off the posteromedial surface of the tibia and mobilized laterally and distally.

Attention is then turned to drilling an 11-mm AL and a 9-mm PM femoral tunnel, performed as described for the double-bundle technique.

The leg is returned to the figure 4 position, and the tibial trough is prepared by creating a vertical arthrotomy between the palpable prominences of the medial and lateral tibial plateaus at the native PCL tibial insertion.

The remaining PCL is identified and débrided, and a ⅛-inch curved osteotome is used to create a trough measuring 13 mm wide, 12 mm deep, and 20 mm long.

A 3.2-mm transtibial drill hole is placed in the trough that corresponds to the 4.5-mm gliding hole in the tibial bone block.

TECH FIG 9 • A. The tibial inlay graft. B. The approach for the tibial inlay begins with a 6-cm incision over the posterior border of the tibia from the crease of the popliteal fossa, which curves distally along the posteromedial border of the tibia. C. The posterior aspect of the tibia after the popliteus muscle has been elevated subperiosteally off the posteromedial surface of the tibia and mobilized laterally and distally. D. The posterior aspect of the tibia after the inlay trough has been created. E. The double-bundle tibial inlay graft after being positioned in the tunnels. F. Lateral radiograph demonstrating the tibial inlay fixation with a 4.5-mm fully threaded cortical screw on the tibial side, and interference screws on the femoral side.
The graft is passed through the joint via an enlarged anteromedial portal into the tibial trough.
- A 4.5-mm fully-threaded cortical screw is used to lag the bone block into the trough.
- Fluoroscopy is used to verify the position of the graft.
- A 4-cm incision is made along the posterior border of the vastus medialis at the center of the medial femoral condyle, and the femoral tunnels are identified.
- The AL and PM bundle grafts are then passed through their respective femoral tunnels using a suture passer.
- Several cycles of flexion and extension are performed to pretension the graft.
- The bundles are secured with metal interference screws placed outside-to-in (TECH FIG 9E,F).
- The AL graft is secured first at 90 degrees flexion, and the PM bundle then is secured at 15 degrees of flexion.
- A gentle anterior drawer is applied during screw insertion to recreate the natural tibial step-off.

Any remaining bone plug protruding from the femoral tunnels is removed with a rongeur, and sutures are tied together over the tunnel bone bridge.

**Tibial Avulsion**
- The PCL tibial avulsion is approached similarly to tibial inlay reconstruction.
- The patient is positioned supine, as in the tibial inlay technique, to facilitate arthroscopic examination.
- The skin incision and the dissection are performed as described for the tibial inlay technique.
- A vertical arthrotomy is made, and the avulsed fragment of the tibia with the attached PCL is identified.
- The bone fragment and PCL are reduced and secured with a 4.0-mm cortical or a 6.5-mm cancellous screw and spiked washer, depending on the size of the fragment.
- The reduction is confirmed with fluoroscopy or a radiograph (TECH FIG 10).

**PEARLS AND PITFALLS**

**Indications**
- Assess for concomitant PLC injury on the EUA and following PCL reconstruction, because deficiency of these structures may lead to PCL graft failure.
- Employ the appropriate technique based on the chronicity of the injury and remaining native PCL.

**Arthroscopy**
- Exposure of the posterior tibia may be tedious but is essential for appropriate, safe tunnel placement.
- When working in the posterior knee joint, be certain the shaver or electrocautery device always faces anteriorly, away from the popliteal vessels.
- Fluid extravasation and lower extremity compartments must be monitored throughout the procedure.

**Tunnel placement**
- A parallel pin guide can be used to make small corrections in tunnel placement.
- Perforate the posterior tibial cortex by hand with the guide pins or reamers in a controlled fashion under direct arthroscopic visualization to avoid neurovascular injury.
- If the patella causes resistance to the acorn reamer when drilling the femoral tunnels, use a smaller reamer to make a starting hole, then hand-dilate the tunnel to the appropriate size with larger reamers.

**Graft management**
- An arthroscopic switching rod, placed via the posteromedial portal between the graft and the posterior tibial cortex, can facilitate graft passage by decreasing friction.
- Avoid penetrating soft tissue with the Beath pin while passing through the anterolateral portal to prevent the graft from getting caught in the soft tissue.

**Fixation**
- An anterior tibial force should be applied during fixation to prevent posterior subluxation.

**Rehabilitation**
- Closed-chain exercises that apply an axial load across the knee protect the PCL reconstruction owing to the sagittal slope of the tibial plateau.
POSTOPERATIVE CARE
- A hinged knee brace is applied and locked in extension. The patient is awakened and taken to the recovery room, where pain and neurovascular status are reevaluated.
- Patients may be kept overnight for pain management and to monitor their neurovascular status.
- Patients are given instructions for exercises (quadriceps sets, straight-leg raises, and calf pumps) and crutch use.
- All dressing changes are performed while an anterior tibial force is applied.
- Patients are instructed to maintain touch-down weight-bearing for 1 week.
- Partial weight bearing is initiated after the first postoperative visit.
- The brace is unlocked after 4 to 6 weeks, and usually is discontinued after 8 weeks.
- Symmetric full hyperextension is achieved, and passive prone knee flexion, quadriceps sets, and patellar mobilization exercises are performed with the assistance of a physical therapist for the first month.
- Mini-squats are performed from 0 to 60 degrees after the first week and from 0 to 90 degrees after the third week.
- Once full, pain-free ROM is achieved, strengthening is addressed.
- The goals for achievement of flexion are 90 degrees at 4 weeks and 120 degrees at 8 weeks.

OUTCOMES
- Choice of graft (autograft vs allograft) has not been shown to affect overall outcome.1
- Acute single-bundle reconstructions have been demonstrated to have significantly better outcomes than chronic reconstructions.6,7
- The clinical outcomes after single-bundle and tibial inlay reconstructions have produced a satisfactory return of function and improvement in symptoms.8,9
- Neither transtibial or tibial inlay has been shown to be superior with regard to overall outcome.7
- No studies have specifically addressed the long-term clinical outcomes of double-bundle reconstructions and PCL augmentation reconstructions.

COMPLICATIONS
- Failure to carefully position the extremity with adequate padding may result in neuropraxia.
- Loss of motion (usually decreased flexion) can result from errors in graft positioning or excessive tensioning during graft fixation. Inadequate rehabilitation also may lead to loss of motion.
- Residual laxity also can occur as a result of graft positioning or failure to address concomitant ligamentous injury.
- Injury to the popliteal vessels is rare, but may be a very serious complication. Care must be taken to prevent overpenetration of the posterior tibial cortex.
- The thigh and calf should be routinely palpated to ensure no compartment syndrome develops from fluid extravasation into the soft tissues.

REFERENCES
DEFINITION

- A medial collateral ligament (MCL) injury usually is the result of a valgus stress on the knee.
- Forced external rotation injuries with a valgus component also have been described as a mechanism that can disrupt the MCL.
- While the direct valgus force is more likely to injure the superficial MCL, external rotation and valgus stress often causes additional injuries to the deep MCL, the anterior cruciate ligament (ACL), the posteromedial corner, or the posterior oblique ligament.
- The most common combined injury is an ACL and MCL injury, followed by meniscus injuries.

ANATOMY

- The medial side of the knee can be divided into three layers: superficial (I); intermediate (II); and deep (III).
- Layer I: the crural fascia extending from the quadriceps fascia into the tibial periosteum
- Layer II: the superficial medial collateral ligament (SMCL) and the medial patellofemoral ligament (MPFL)
- Layer III: the deep MCL (ie, the meniscotibial and meniscofemoral ligaments) and the posteromedial corner (ie, semimembranosus and posterior oblique ligament [POL])
- The superficial MCL originates from the medial femoral epicondyle. It inserts approximately 4 to 6 cm distal to the medial joint line and can be divided into an anterior and a posterior portion. The anterior portion tightens in flexion; the posterior portion tightens in extension.
- The deep MCL tightens in knee flexion and is lax in full knee extension.
- The posteromedial corner provides rotational stability to the medial side of the knee. Injuries to these structures cause anteromedial rotatory instability.
- The semimembranosus has five main attachments to the posterior capsule of the knee:
  - Pars reflexa, attaching directly to the proximal medial tibia
  - Direct arm, attaching to the posteromedial tibia
  - Insertion to the proximal medial capsule
  - Attachment to the POL
  - Attachment to the popliteus aponeurosis

PATHOGENESIS

- The typical mechanism for an MCL injury is a valgus stress acting on the knee joint with the foot planted. This mechanism often leads to a disruption of the deep and superficial MCL.
- If an external rotational component is added, a disruption of additional restraints such as the ACL and the posteromedial corner is likely. In particular, an injury to the POL indicates a significant capsular injury that leads to a higher grade of medial and rotatory instability.5
- MCL injuries can be partial or complete. A complete MCL injury involves disruption of the superficial and deep MCL and usually results initially in inability to ambulate.
- MCL injuries can be on either the femoral or tibial side. It is important for the treatment algorithm to differentiate whether the tear involves the femoral origin of the MCL or the tibial insertion.

NATURAL HISTORY

- Acute isolated MCL injuries usually are treated nonoperatively with protective weight bearing and bracing for 2 to 6 weeks.
  - In particular, partial tears of the MCL (grade I or II) heal well with conservative treatment.
  - Complete MCL injuries (grade III injuries) initially can be treated conservatively if they are femoral-based ligament ruptures.3
- A complete tibial-sided MCL avulsion with POL extension is less likely to tighten up with nonoperative management and may require repair or reconstruction.
- Grade 3 MCL injuries in combination with other ligament injuries of the knee may require acute surgical repair in case of a complete tibial avulsion with POL extension.5

PATIENT HISTORY AND PHYSICAL FINDINGS

- A description of the mechanism of injury (eg, valgus mechanism, valgus rotation mechanism) must be elicited.
- The examination includes inspection for peripheral hematoma along the medial side of the knee, palpation of hamstrings, joint line (meniscal injury) and the femoral origin and tibial insertion of the MCL stability testing.
- Valgus stress at 0 and 30 degrees: grade 1 (0- to 4-mm opening) and 2 (5- to 9-mm opening) injuries usually can be treated nonoperatively; grade 3 (10- to 15-mm opening) injuries are associated with other ligament tears (ie, ACL, POL) in over 75% of cases.
- Slocum’s modified anterior drawer test: disruption of the deep MCL allows the meniscus to move freely and allows the medial tibial plateau to rotate anteriorly, leading to an increased prominence of the medial tibial condyle.
- Anterior drawer test in external rotation: disruption of the MCL alone should not lead to an increased anteromedial translation. An increased anteromedial translation indicates an anteromedial rotatory instability that involves an injury of the posteromedial capsule (eg, POL, semimembranosus attachments, as well as deep MCL).
- A thorough examination of the knee should always include the following assessments:
  - Meniscus: tenderness directly at the joint line is a sensitive sign for a meniscus injury. The McMurray test or a flexion–rotation–compression maneuver may accentuate medial
joint line pain, suggesting a medial meniscus tear. (This test may not be helpful in an acute setting.)
- ACL: An immediate (within 24 hours) intra-articular effusion after the injury indicates a high likelihood of ACL injury. Positive Lachman test (acute) and pivot shift test (chronic) indicate an associated ACL tear. In the acute or subacute setting, these tests may be difficult to perform. Instrumented laxity testing (KT-1000) may be helpful in these situations. An increased valgus laxity in full extension almost always indicates something more than an MCL injury.
- PCL: A positive posterior drawer test indicates a PCL injury. The endpoint is important to assess the grade of the PCL injury.
- Patella: The apprehension sign and localized tenderness on the lateral or medial aspect of the patella or the lateral trochlea indicates a possible patella dislocation, which can go hand-in-hand with an intra-articular effusion. Tenderness at the medial femoral epicondyle also can be caused by an avulsion of the MPFL.

IMAGE AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs help to assess the bony integrity of the knee joint. They may show indirect signs of ligament injury (eg, Segond fracture), but they usually are not helpful for the diagnosis of an acute MCL injury.
- In the case of chronic MCL instability, a Pellegrini-Stieda lesion (bony spur originating at the femoral origin of the MCL, usually visualized on the flexion weight-bearing posteroanterior radiograph) may be present (FIG 1A).
- MRI with or without contrast is helpful to identify medial collateral ligament damage.
- Edema or MCL disruption can be visualized.
- The location and extent of the disruption (femoral vs tibial) can be determined.
- The amount of bone bruising can be assessed, and associated pathology (eg, meniscal tears, ACL tears, posteromedial corner injuries) can be visualized.
- Arthroscopic examination is a formidable tool to assess the true nature of the MCL injury.
- An ipsilateral “drive-through” sign (ie, opening of the medial compartment of more than 10 mm, allowing for complete insertion of the arthroscope into the medial compartment [FIG 1B]) should arouse suspicion for a significant MCL injury that may require repair or reconstruction.
- The location of the acute or chronic injury —femoral or tibial—also can be evaluated. Separate injuries of the POL also can be visualized (FIG 1C).

DIFFERENTIAL DIAGNOSIS
- Medial meniscus tear
- ACL tear
- Posteromedial corner injury
- Patella dislocation
- Pes-anserine bursitis

NONOPERATIVE MANAGEMENT
Grade 1 and 2 Medial Collateral Ligament Sprains
- Rest, ice compression, elevation (RICE) for 24 hours or until swelling is controlled
- Once swelling is controlled, partial weight bearing, range-of-motion (ROM) exercises, and electrical stimulation can be started. A simple hinged brace is applied.
- Full weight bearing can be allowed once ROM over 90 degrees of flexion as well as motor control of the thigh muscle has been demonstrated.\(^2,4\)
- Once full ROM and 80% strength of the opposite side have been achieved, closed kinetic chain exercises, jogging, and treadmill exercise may begin.
- In athletes, a return to sport-specific training is safe once 80% of the maximum running speed is achieved.\(^2,4\)
- Return to play depends on the grade of the sprain:
  - Grade 1: 10 to 14 days
  - Grade 2: 3 to 4 weeks

Grade 3 Medial Collateral Ligament Sprains
- MCL sprains without associated ACL or meniscus tear account for less than 20% of all grade 3 sprains.
- The knee is re-evaluated frequently (every 7 to 10 days) to assess whether the MCL “tightens up.” Tibial-sided complete avulsions of the MCL may not heal and require acute surgical repair if they do not tighten up within the first 4 weeks.
- It is important to check for combined ACL/MCL tears. Grade 3 MCL tears with POL extension in combination with
an acute ACL tear often require surgical repair or even augmentation because of the rotational laxity that results from the POL injury.

- **RICE** is maintained until the swelling is controlled.
  - 0 to 4 weeks: restoration of ROM, quadriceps/hamstring strengths, normal gait pattern, full weight bearing with hinged knee brace
  - 4 to 6 weeks: full ROM, full quadriceps/hamstring strengths, closed kinetic chain exercises, stair-stepper exercise, proprioceptive exercises
  - 6 to 10 weeks: full squatting, jogging, light agility drills, slow return to competition, brace discontinued for non-contact sports

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- All radiographs and MRIs are reviewed before surgery.
- Associated injuries must be addressed at the same time and often determine the sequence of the surgery (PCL before ACL before MCL)

**TECHNIQUES**

**INCISION AND DISSECTION FOR MID-MEDIAL APPROACH**

- The incision should be centered over the joint line and can be extended proximally or distally, as necessary.
- In case of a proximal extension, the incision should be slightly curved posteriorly over the medial femoral epicondyle.
- Retraction of the skin exposes the sartorius fascia, which must be split in a longitudinal or T fashion. Underneath the sartorius fascia (layer I), the superficial MCL is exposed.
- The posterior border of the superficial MCL and the anterior border of the POL are identified, and a vertical incision is made along this interval, exposing the deep MCL.
- This incision can be carried down through the capsule to expose the meniscal attachments. An avulsion of the POL from the posterior capsule may be identified in select cases.
- A plane can be developed between the superficial and the deep MCL.
- This plane allows for a separate repair of the deep MCL against the POL to tension the POL.
- It also exposes the medial tibial plateau and allows for easy placement of a suture anchor for a repair of the deep MCL at the level of the joint line, which is critical.

**ACUTE REPAIR OF TIBIAL-SIDED ISOLATED GRADE 3 MCL TEARS**

- Tibial avulsion is documented arthroscopically by a positive "drive-through" sign (>10 mm of medial opening).
  - The medial meniscus lifts off from the tibial plateau during this maneuver, revealing the tibial-sided tear of the deep MCL.
  - A limited direct medial approach is performed through a 5- to 6-cm incision along the posterior aspect of the MCL.
  - The sartorius fascia is divided, which usually exposes acute avulsion of the deep MCL from the tibia. The superficial MCL also usually is torn but can be sharply divided from the deep MCL.
  - Three or four double-loaded suture anchors are then placed along the medial border of the tibial plateau about 5 mm below the joint line.
  - The meniscotibial ligament can be secured to the suture anchors, allowing for an excellent repair of the deep MCL along with the coronary ligament and medial meniscus.
  - The sutures can be left long after the initial knots are tied and also can be used to tie down the superficial MCL (**TECH FIG 1**).
AUTOGRAFT RECONSTRUCTION OF ISOLATED CHRONIC MCL TEARS

- Reconstruction of the superficial MCL requires stabilization of the central pivot of the knee. Any associated ACL or PCL injury must be addressed simultaneously with or before the MCL reconstruction.
- The reconstruction includes repair and tightening of the deep MCL/POL complex, which should be tightened at 0 degrees. The superficial MCL reconstruction should be tightened at 30 degrees of flexion.
- The deep MCL and POL can be identified through the midmedial incision and can be retightened using suture anchors, as with the primary repair of the MCL (TECH FIG 2A,B).
- Chronic MCL injuries should be augmented with a superficial MCL reconstruction.
- Autograft MCL reconstruction can be done using a Bosworth reconstruction.
- In the Bosworth reconstruction, a semitendinosus tendon is harvested using the open or closed tendon stripper. The femoral origin of the MCL is identified. A K-wire is inserted into the insertion site, and isometry is tested to avoid a flexion contracture after the superficial MCL repair.
- Once the isometric site is identified, the semitendinosus can be routed around a screw and washer femorally and can be attached distally using a staple or bone tunnels. This allows for reconstruction of the posterior and anterior bundles of the superficial MCL (TECH FIG 2C,D).

ALLOGRAFT RECONSTRUCTION OF ISOLATED CHRONIC MCL TEARS

- Borden et al\(^1\) have described an allograft reconstruction of the MCL.
- A double anterior tibialis tendon or a split Achilles or patella tendon can be used for this technique.
- The surgical approach is the same as that described for autograft reconstruction.
- The origin of the MCL on the medial epicondyle must be identified. The femoral fixation is positioned at the anatomic insertion of the MCL.
- Fixation can be achieved in various ways—bone tunnel using a soft tissue screw fixation, bone block using an interference screw fixation, bone trough, or screw and washer fixation.
Chapter 45  REPAIR OF ACUTE AND CHRONIC KNEE MEDIAL COLLABORAL LIGAMENT INJURIES 379

- The distal tibial fixation has to reconstruct the anterior and posterior aspect of the native MCL (TECH FIG 3).
- The allograft can be anchored anteriorly and posteriorly along the anatomic attachment sites using an interference screw (as depicted), a screw and washer, or a staple.

**Distal Fixation in Chronic Injuries**

- In chronic MCL injuries, it often is the distal end of the MCL that has failed to heal.

- Using the standard medial approach, the distal end of the MCL often can be identified (TECH FIG 4A).
- This attachment can be used in the reconstruction if the length is adequate; if not, it can be sutured to the reconstruction.
- The allograft is then fixed femorally (as described earlier) and routed along the course of the superficial MCL (TECH FIG 4B).
- The posterior and anterior portions of the superficial MCL can then be individually attached to the tibia.

**POSTOPERATIVE CARE**

- The postoperative course is as follows:
  - 0 to 3 weeks: touch-down weight bearing, hinged brace locked in 30 to 90 degrees of flexion, hamstring/quadriceps strengthening in brace
  - 3 to 6 weeks: progress to full weight bearing, ROM free in brace, quadriceps/hamstring strengthening, closed kinetic chain exercises. The repair must be protected.
  - 6 to 12 weeks: the brace is discontinued. Light jogging and stair-stepper exercise are begun.
  - 12 to 18 weeks: progressive return to sports with sport-specific drills and return to play once 90% of quadriceps and hamstring strength and 75% of maximum running speed have been regained.

**OUTCOMES**

- Grade 1 and 2 MCL sprains should be treated nonoperatively. The average time to return to athletic activities is between 19 and 23 days, on average, for grade 1 and 2 injuries, respectively.
Grade 3 MCL sprains can be treated nonoperatively with good success if several pitfalls are avoided:

- Conservative treatment of an isolated Grade 3 MCL injury allows most athletes to return to play after an average of 34 days.\(^2\)
- Tibial-side avulsions of the deep and superficial MCL with POL extension tend to progress toward chronic MCL laxity. Either early surgical treatment or repetitive clinical examination to assess the gradual return of valgus stability over the course of 4 weeks is advisable. If valgus laxity is still present after 4 weeks, surgical treatment is advised.
- Concomitant ACL injuries are common and often will result in residual chronic MCL laxity if treated nonoperatively.

COMPLICATIONS

- Failure to diagnose associated ligament, meniscal, and articular cartilage injuries
- Deep venous thrombosis
- Infection

REFERENCES

DEFINITION
The posterolateral corner (PLC) of the knee is a complex area, both anatomically and functionally, that has the potential to cause great disability when injured.
- Injuries to the structures of the PLC are uncommon, accounting for only 2% of all acute ligamentous knee injuries.
- Because of the high incidence of combined ligament injuries associated with PLC injuries, other ligament injuries in the knee always should be suspected when treating the PLC.
- Conversely, cruciate ligament reconstructions have a tendency to fail if PLC injuries are left untreated, so one must always have a high index of suspicion for PLC injuries when treating other injuries in the knee.
- The significance of a PLC knee injury can be great.
- Chronic instability due to the untreated PLC injury can be debilitating.
- The complex biomechanical relationships among the structures of the PLC are important in resisting varus and external rotation forces.
- Insufficiency in the posterolateral structures of the knee can lead to a varus-thrust gait and the sensation of instability, especially when the knee is in extension during the toe-off phase of walking.
  - The convexity of the lateral tibial plateau and lateral femoral condyle may contribute to this instability.
  - This instability may hinder stair-climbing or cutting activities, and patients may complain of lateral knee pain.
  - Chronic PLC insufficiency also may lead to tricompartmental degenerative joint disease.
  - An increase in patellofemoral joint contact pressure has been found to occur with PLC and posterior cruciate ligament (PCL) sectioning in cadaveric studies.

ANATOMY
Before treating a patient with a PLC injury, one must be familiar with the complex anatomy of the area.
- The PLC is made up of both dynamic and static stabilizers.
- Seebacher et al organized the posterolateral structures into three layers.
  - The superficial layer is made up of the iliotibial tract anteriorly and the biceps femoris posteriorly.
  - The common peroneal nerve lies deep and posterior to the biceps femoris in this layer at the level of the distal femur.
  - The iliotibial (IT) tract or band, which inserts on Gerdy’s tubercle on the tibia, is tight and moves posteriorly in knee flexion. It actually places an external rotational force on the tibia during knee flexion. During knee extension, the IT band moves anteriorly and becomes less taut. Because of its relaxed state in knee extension, this structure rarely is injured in PLC injuries, so it is a good reference point for the location of other structures in surgery.
- The biceps femoris inserts on the fibular head, but also has attachments to the IT band, Gerdy’s tubercle, the lateral collateral ligament (LCL), and the posterolateral capsule. It adds dynamic stability to the PLC.
- The middle layer of the PLC consists of the quadriceps retinaculum anteriorly, the patellofemoral ligaments posteriorly, and the patellomeniscal ligament.
  - These structures add accessory static stability to the PLC.
- The deep layer, which is the most important, consists of the lateral part of the joint capsule and the coronary ligament, which inserts on the lateral meniscus; the popliteus tendon and the popliteofibular ligament; the arcuate ligament; the LCL; and the fabellofibular ligament.
  - The popliteus originates on the posterior tibia, passes through the hiatus of the coronary ligament, and inserts on the lateral femoral condyle. It also has attachments to the lateral meniscus.
  - The popliteofibular ligament exists as a direct static attachment of the popliteus tendon from the posterior tibial head to the lateral femoral epicondyle.
  - The arcuate ligament is a Y-shaped ligament that reinforces the posterolateral capsule of the knee and runs from the fibular styloid to the lateral femoral condyle. In radiographs, the arcuate fracture shows an avulsion of this ligament off of the fibular styloid.
  - The LCL originates on the lateral epicondyle of the femur and inserts on the fibular head. This ligament is the primary static restraint to varus stress from 0 to 30 degrees of knee flexion. The LCL becomes progressively more lax in greater degrees of flexion, however. Aponeurotic layers of the biceps femoris provide tension to the LCL to assist in dynamic resistance to varus stress. The LCL also provides resistance to external rotation stress.
- Much anatomic variation has been noted in the structures of the deep layer, especially the arcuate and fabellofibular ligaments.
- Hughston et al described the importance of an arcuate ligament complex consisting of the LCL, arcuate ligament, popliteus, and the lateral head of the gastrocnemius. This complex acts as a “sling” of static and dynamic restraint to rotation of the lateral tibiofemoral articulation.

PATHOGENESIS
PLC knee injuries most commonly are caused by sports injuries (40%), motor vehicle accidents, and falls.
- Any mechanism that can cause a knee dislocation theoretically can cause an injury to the PLC.
- The most common mechanism for an isolated PLC injury is hyperextension of the knee with a varus moment. This mechanism can be caused by blunt posterolaterally forced trauma to the medial proximal tibia, such as a helmet to the knee in football.
Other mechanisms of injury include hyperextension alone, hyperextension with an external rotation force, a severe varus force alone, or a severe external rotation torque to the tibia.

As mentioned earlier, an isolated PLC knee injury is rare. A flexed knee with tibial external rotation and posterior translation can cause a PCL/PLC combined injury.

**NATURAL HISTORY**

Posterolateral knee injuries rarely occur as isolated ligament disruptions. They most often are associated with injury to the PCL, the ACL, or both. Therefore, the true natural history of these injuries is unknown.

If left untreated, they will contribute to failure of other ligament reconstruction.

Repair, and often supplementation with exogenous grafts, is recommended in all cases of combined PLC injury.

**HISTORY AND PHYSICAL FINDINGS**

Methods for examining the PLC include the following:

- **Dial test.** More than 10 degrees difference between limbs is consistent with ligamentous PLC injury. Increased rotation at 30 degrees but not at 90 degrees indicates isolated PLC injury. Increased rotation at both 30 degrees and 90 degrees indicates PLC and PCL injuries.
- **Posterolateral external rotation test.** Increased posterior translation and external rotation at 90 degrees are suspicious for PLC or PCL injury. Subluxation at 30 degrees is consistent with isolated PLC injury.
- **Posterior drawer test (PCL testing).** More than 10 mm translation is highly suggestive of multiligamentous knee injury.
- **Varus stress test (LCL testing).** An isolated tear of the LCL causes maximal varus angulation at 30 degrees.
- **Quadriceps active test.** Forward translation of the tibia after attempted knee extension is positive for PCL insufficiency (reduction of posterior tibial sag).
- **Gait.** The patient may walk with a slightly flexed knee to avoid pain and instability with hyperextension of the knee. Varus thrust also may be present.
- **Reverse pivot-shift test.** Palpable shift of the lateral tibial plateau is positive, but not specific for PLC injury. This test is difficult to perform on the awake patient.
- **External rotation recurvatum test.** Hyperextension and increased varus of the knee and external rotation of the tibia are positive for PLC injury.
- **Range of motion (ROM).** The normal range is 0 to 135 degrees of motion. Loss of extension may be due to a displaced meniscus tear. Loss of flexion may be due to effusion.
- **Effusion.** A large effusion suggests other intra-articular pathology, such as an ACL or PCL tear or a peripheral meniscus tear. Effusion may be diminished if the capsule is torn.
- **Neurovascular examination (serial).** The incidence of popliteal artery injury is increased in knee dislocations. An arteriogram should be obtained if the vascular examination is different from that in the contralateral leg. The incidence of peroneal nerve injury is increased by 10% to 33% with PLC injuries.
- **It is important to obtain a good history from the patient with an acute PLC injury.**
Pain and swelling of the posterolateral knee are common.

A rapid knee effusion suggests the possibility of intra-articular pathology, such as a cruciate ligament injury or peripheral meniscus tear.

It also is important to obtain history about the presence or absence of a true tibiofemoral dislocation, because there is an association between PLC injuries and knee dislocations.

Neurologic changes also must be investigated because of the increased incidence of peroneal nerve injuries in the patient with an injured PLC.

Patients with chronic posterolateral instability commonly present with the sensation of instability with the knee in extension and lateral or posterolateral aching pain in the knee.

PLC injuries can be graded as 1, 2, or 3.

Grade 1 injuries involve minimal tearing of the ligaments and are not associated with abnormal joint motion.

Grade 2 injuries have partial tearing, but still have no abnormal joint motion.

Grade 3 injuries have complete tearing of the ligaments and abnormal joint motion.

Hughston et al graded PLC injuries based on ligamentous instability. Cases of mild, moderate, and severe instability are graded as 1+, 2+, and 3+, respectively.

Because PLC knee injuries have such a high association with combined ligament injuries, a careful examination for other knee pathology is necessary.

PCL injury can be recognized by a positive posterior drawer test, tibial sag or recurvatum, and hemarthrosis.

A positive Lachman test is the most sensitive test for an ACL tear. The examiner should not be fooled by a false endpoint caused by a tight effusion or a displaced meniscal tear. A positive pivot shift also is a sensitive test for an ACL tear, although it is difficult to perform on an acute patient because of discomfort.

Meniscal tears can also be associated with PLC injuries. Joint line tenderness is the most sensitive test for meniscal tears. A lateral meniscus tear may give lateral-sided knee pain, which could be confused with a posterolateral knee injury. Mechanical symptoms also raise concern for meniscal tears. Loss of full extension of the knee hints at the possibility of a locked bucket handle meniscus tear.

Although it is rare to have LCL and medial collateral ligament (MCL) tears in the same injury, one must examine all ligaments of the knee in a traumatic injury. The MCL is tested by valgus stress at 0 and 30 degrees of knee flexion.

Laprade and Wentorf recommend obtaining not only the standard coronal, sagittal, and axial cuts of the knee but also coronal oblique 2-mm thin cuts to include the entire fibular head and styloid, to better evaluate the popliteus tendon and the LCL.

Laprade and Wentorf also recommend using a magnet with a signal of at least 1.5 T.

MRI is useful in evaluating the soft tissues of the knee and for evaluating the bone for contusions or edema.

A bony contusion of the anteromedial femoral condyle is concerning for a PLC injury.

Arthroscopy can be useful in diagnosing posterolateral ligament pathology.

An avulsion of the popliteus off of the femur can be visualized directly, as can injuries to the coronary ligament of the posterior horn of the lateral meniscus.

The “drive-through” sign is another arthroscopic finding in the patient with a PLC injury. This is defined as more than 1 cm of the lateral joint line opening to varus stress during arthroscopic evaluation of a posterolaterally insufficient knee.

**IMAGING AND DIAGNOSTIC STUDIES**

The initial diagnostic imaging examination should begin with standard anteroposterior (AP) and lateral radiographs of the knee.

Laprade and Wentorf recommend obtaining full-length standing AP radiographs to evaluate for varus malalignment in chronic patients.

Plain radiographs may show increased joint space laterally or a frank knee dislocation.

Plain radiographs also can be obtained to evaluate associated fractures, such as an arcuate avulsion fracture of the fibular head, a Gerdy’s tubercle avulsion, and a Segond fracture, which is an avulsion of the lateral capsule off of the tibia.

Segond fractures typically are thought to be associated with ACL injuries, but they also can be associated with posterolateral ligament injuries.

Patellofemoral or tricompartmental arthritis may be associated with chronic instability. Typically, the lateral compartment is more involved than the medial compartment.

An effusion in the suprapatellar pouch also can be visualized on plain radiographs and hints at the presence of an intra-articular pathology, such as an ACL or PCL tear.

Varus stress films may be used to evaluate the integrity of the LCL as well.

MRI also is helpful in evaluating a PLC injury.

Laprade et al recommend obtaining not only the standard coronal, sagittal, and axial cuts of the knee but also coronal oblique 2-mm thin cuts to include the entire fibular head and styloid, to better evaluate the popliteus tendon and the LCL.

Laprade and Wentorf also recommend using a magnet with a signal of at least 1.5 T.

MRI is useful in evaluating the soft tissues of the knee and for evaluating the bone for contusions or edema.

A bony contusion of the anteromedial femoral condyle is concerning for a PLC injury.

Arthroscopy can be useful in diagnosing posterolateral ligament pathology.

An avulsion of the popliteus off of the femur can be visualized directly, as can injuries to the coronary ligament of the posterior horn of the lateral meniscus.

The “drive-through” sign is another arthroscopic finding in the patient with a PLC injury. This is defined as more than 1 cm of the lateral joint line opening to varus stress during arthroscopic evaluation of a posterolaterally insufficient knee.

**FIG 2** Lateral compartment. Arthroscopic views demonstrating popliteal tendon injury (A) and excessive opening, or “drive-through” sign (B).
DIFFERENTIAL DIAGNOSIS

- Lateral meniscus tear
- Other ligamentous injury (e.g., PCL, ACL)
- Tibial plateau fracture
- Supracondylar femur fracture
- Contusion
- Degenerative joint disease with varus malalignment

NONOPERATIVE MANAGEMENT

- Grade 1 and most grade 2 posterolateral ligament injuries of the knee usually are treated successfully without surgery.2 These patients typically do well without significant lingering symptoms or instability.
- For grade 1 and 2 injuries, patients are immobilized for 2 to 4 weeks in either an immobilizer or cast.
- Quadriceps sets and straight leg raises are allowed in the immobilizer only.17
- Weight bearing also is restricted during this period.17
- After 3 or 4 weeks in an immobilizer, protected ROM exercises are initiated in a hinged knee brace.
- The patient is allowed to bear weight as tolerated, and closed-chain quadriceps strengthening is begun.
- Hamstring strengthening is avoided for 6 to 10 weeks after injury.17
- Because of altered gait mechanics, formal gait instruction also should be initiated once the patient begins weight bearing.
- Although patients with grade 1 or 2 injuries typically do well with nonoperative treatment, residual laxity and instability may require surgical intervention.

SURGICAL MANAGEMENT

- Grade 3 PLC injuries tend to do poorly with nonoperative management.11
  - Indications for operative treatment of PLC injuries consist of 5 to 10 mm of opening to varus stress at 30 degrees of knee flexion and a positive dial test or posterolateral external rotation test.2 These findings are consistent with a grade 3 PLC injury.
- Ideally, PLC injuries should be treated between 10 days and 3 weeks after injury.2,4,12,23
  - Before 10 days, the knee usually is significantly swollen and still is in the acute inflammatory stage of the injury.
  - It also is possible to regain some quadriceps tone and ROM if surgery is postponed more than 10 days. Theoretically, the risk of arthrofibrosis would, therefore, be diminished.2,3
  - Waiting more than 3 weeks to operate results in increased scarring and difficulty in repairing the posterolateral structures primarily.23

  - Identifying and protecting the peroneal nerve becomes more difficult with increased scarring.17
  - Results of chronic repair are inferior to those of acute repair.2

Preoperative Planning

- In treating posterolateral ligament injuries, one must decide whether to repair the torn structures primarily, augment the repair, do an advancement, or perform a reconstruction of the posterolateral corner using allograft or autograft.
- Much of the preoperative planning is contingent on whether the PLC injury is isolated or combined with other ligamentous injuries.
- Preoperative radiographs are important to evaluate for fractures or other bony abnormalities.
- Hip-to-ankle films may be helpful in chronic cases to evaluate for varus malalignment.
- MRI helps evaluate for other associated ligamentous or meniscal injuries and should be used in preoperative planning if possible.
- If cruciate ligamentous injuries exist, they should be reconstructed prior to or concurrently with the PLC repair and reconstruction; otherwise, there is an increased risk that the PLC reconstruction will fail.2

Positioning

- Positioning for posterolateral surgery is contingent on the presence of other ligamentous injuries.
- Placing the patient in a lazy lateral position with a beanbag allows the surgeon to rotate the hip and leg externally for arthroscopic and cruciate ligament work as well as to internally rotate the leg into the lateral decubitus position for the lateral knee work.
- We have found a foot holder to be helpful for arthroscopic work.
- A well-padded tourniquet is placed high on the patient’s thigh to avoid interference with the operative field.

Approach

- Arthroscopic visualization of the lateral compartment may demonstrate injuries or excessive opening (the “drive-through” sign).
- After arthroscopy and additional procedures, as indicated, the surgical approach is carried out as described in Techniques.
Chapter 46  MANAGEMENT OF POSTEROLATERAL CORNER INJURIES

TECH FIG 1 • Exposure begins with an incision along the posterior border of the iliobial band.

DIRECT PRIMARY REPAIR

- For best results, primary repair should be done within 2 to 3 weeks of injury.17
- The structures should be repaired with the knee in 60 degrees of flexion and neutral tibial rotation.23
- A tibial avulsion of the popliteus can be repaired directly to the posterolateral tibia using suture anchors, sutures, or a cancellous screw with soft tissue washer (TECH FIG 2).
- A femoral avulsion of the popliteus typically occurs with an avulsion of the LCL.
  - Both of these structures can be sutured back to the lateral femoral condyle using transosseous drill holes.
- Laprade and Wentorf17 described the use of a recess procedure for treatment of a femoral avulsion of the popliteus or LCL.
  - In this procedure, a whipstitch is placed in the proximal popliteus, a small bone tunnel is made at the original femoral insertion of the popliteus, a stylette pin is used to pass the sutures from the whipstitch to the medial side of the knee, and the popliteus is pulled into the tunnel with the sutures.
  - The sutures are then tied over a button medially.
- A popliteofibular ligament avulsion off the fibula can be treated with tenodesis of the popliteus tendon to the posterior fibular head using suture anchors.2
  - The tenodesis can be reinforced with the fabellofibular ligament.
  - An avulsion of the LCL and arcuate ligament off of the fibular head can be reattached with transosseous sutures into the fibular head.2

TECH FIG 2 • Direct primary repair of the popliteus tendon using a transosseous suture and button.

AUGMENTATION

- If the repair of the structures of the PLC is tenuous or the tissue is poor, the surgeon should consider augmentation of the repair.
  - The tibial attachment of the popliteus can be augmented with a strip of IT band left attached distally to Gerdy’s tubercle (TECH FIG 3A).
  - The strip is passed through a drill hole in the proximal tibia from anterior to posterior and sutured to the popliteus.2
- Terry and Laprade27 described three fascial incisions for exposure of the PLC:
  - The first incision bisects the IT band.
  - The second incision is made between the posterior border of the IT band and the short head of the biceps femoris.
  - The third incision is made along the posterior border of the long head of the biceps.
- A capsular incision can be made along the anterior border of the LCL.
  - The popliteofibular ligament can be augmented using a central slip of the biceps femoris.29
  - The biceps distal attachment is left intact, and the slip is sutured to the posterior fibula, passed under the remaining biceps posteriorly, and attached to the lateral femur with suture anchors or screw and soft tissue washer (TECH FIG 3B).
**ADVANCEMENT**

- In the patient in whom the posterolateral structures are insufficient for primary repair or in chronic cases, an arcuate complex advancement can be performed.\(^{10}\)
- The LCL must be of normal integrity, and the popliteofibular ligament must be intact.
- The LCL, popliteus, lateral gastrocnemius, arcuate ligament, and posterolateral capsule are advanced en bloc in line with the LCL, tensioned with the knee at 30 degrees of flexion and neutral tibial rotation, and inserted into a trough in the distal lateral femur (TECH FIG 4).
- The disadvantage of this procedure is that the advancement does not restore isometry, thus leading to stretching of the reconstruction over time.\(^{20}\)

**TECH FIG 4** • Proximal arcuate complex advancement. The lateral collateral ligament (LCL), popliteus, lateral head of the gastrocnemius, arcuate ligament, and posterolateral capsule are advanced and inserted en bloc to the distal lateral femur.

**RECONSTRUCTION**

- Reconstruction of the posterolateral corner is used in acute injuries when the tissue is poor or irreparable and in chronic cases in which the tissues are scarred and attenuated.
- The lateral collateral ligament, the popliteofibular ligament, and the popliteus are the three most important structures to be reconstructed in the PLC.\(^{20}\)
- Reconstruction of the lateral collateral ligament using local tissue, allograft, and autograft has been described.
**BICEPS TENODESIS TECHNIQUE**

- Clancy et al. reconstructed the lateral collateral ligament using a biceps tenodesis technique (TECH FIG 5).
- In this technique, the entire biceps is transferred to the lateral femoral condyle 1 cm anterior to the LCL origin.
- The distal biceps is left attached to the fibular head.
- Disadvantages of this technique are that it does not reconstruct the popliteus or popliteofibular ligament, and it sacrifices the dynamic stabilizing effect of the biceps femoris.

**Collateral Ligament Reconstruction**

- Isolated LCL reconstruction also can be performed using Achilles tendon allograft, patellar tendon auto- or allograft, or a central tubularized slip of the biceps tendon (TECH FIG 6).
  - Fluoroscopy can be used to ensure proper placement of the proximal end of the graft to the lateral femoral epicondyle.
  - Plication of the remaining posterolateral structures can be performed.

**Two-Graft Technique**

- Laprade et al. have described an anatomic posterolateral knee reconstruction (TECH FIG 7) using a two-graft technique (ie, Achilles tendon allograft split in half).
- The first graft is used to reconstruct the popliteus.
  - The bone plug is secured in the anatomic location of the popliteus insertion on the femur, and the graft is passed from posterior to anterior through an anatomically placed tibial tunnel.
- The second graft is used to reconstruct both the LCL and the popliteofibular ligament.
  - The bone plug is secured in the femoral tunnel at the anatomic location of the LCL origin.
The graft is then passed through a tunnel from lateral to posteromedial and then pulled through the same tibial tunnel from posterior to anterior.

Interference screws are used to secure the grafts in their tunnels, and soft tissue staples are used for secondary fixation.

**Split Patellar Tendon Technique**

Veltri and Warren\(^2^9\) have described a technique of reconstructing the PLC using a split patellar tendon allograft or autograft (TECH FIG 8).

- The patellar bone plug is fixed in a tunnel in the lateral femoral condyle using a suture button on the medial femoral cortex.
- The graft is then split. The anterior limb is brought from posterior to anterior through a tunnel in the fibular head reproducing the popliteofibular ligament. The posterior limb is brought through a tibial tunnel from posterior to anterior. Both limbs are secured with suture buttons.
- A central slip of biceps can be used to reconstruct the LCL, as described earlier.
**Popliteus Bypass Technique**

- Muller\(^2\) described a popliteus bypass technique (TECH FIG 9) in which a free graft is passed through a tibial tunnel from anterior to the posterolateral proximal tibia and secured to the anterior aspect of the lateral femoral condyle.
- This technique does not reproduce either the LCL or the popliteofibular ligament.

**Figure 8 Technique**

- Semitendinosus and gracilis autograft have been used to reconstruct the popliteofibular ligament and LCL concurrently.
- Larson\(^18\) described a figure 8 technique in which he used hamstring autograft passed through a fibular tunnel, crossed in a figure 8 pattern, and wrapped around a screw and soft tissue washer at an isometric point on the lateral femoral condyle (TECH FIG 10).

**Lateral Collateral Ligament Reconstruction Using Bone–Patellar Tendon–Bone Allograft**

- Lattimer et al\(^19\) described using a bone–patellar tendon–bone allograft fixed distally to the fibular head with an interference screw and proximally to the lateral femoral condyle 5 mm anterior to the femoral origin of the LCL.
- The graft is tensioned with a valgus force placed on the 30-degree flexed knee.
- The large cross-sectional area of the graft theoretically restores LCL and arcuate and popliteofibular ligament function.
- This reconstruction neglects the popliteus, however.

**Authors’ Preferred Technique**

- We have found at our institution that a combination of the Larson and Muller techniques is the most effective approach to reconstructing the LCL, popliteofibular ligament, and popliteus.
PEARLS AND PITFALLS

- Monitor for fluid extravasation and increased compartment pressures during the arthroscopic portion of the procedure, because the capsule usually is disrupted in PLC injuries.
- Do not miss PLC injury when treating cruciate ligament injuries, to avoid failed cruciate ligament reconstruction.
- Reconstruct the cruciate ligaments before or concurrently with PLC reconstruction.
- Repair structures of the PLC beginning from deep to superficial.
- Varus malalignment may lead to failed PLC reconstruction; therefore, valgus osteotomy may be needed in chronic PLC insufficiency.
- Determine safe ROM of the knee before leaving the operating room, to guide postoperative rehabilitation.

POSTOPERATIVE CARE

- A hinged knee brace locked in extension should be used, and protected weight bearing should be followed for 3 weeks following a reconstruction and 6 weeks following a direct primary repair.2,17
  - Weight bearing theoretically places tension on the repair because of the normal mechanical axis of the leg.
  - Straight leg raises may be allowed in the knee brace initially.
  - Active knee extension and closed chain kinetic quadriiceps strengthening may be initiated at 4 to 8 weeks postoperatively.
  - Gentle leg presses, proprioceptive training, and squats may be initiated at 3 months.
  - Hamstring exercises should be strictly avoided until 12 to 16 weeks postoperatively.2,17
  - A fairly intensive rehabilitation protocol should be followed for 9 to 12 months.
  - The goal of rehabilitation is to achieve symmetrical quadriiceps strength, knee stability, and full knee ROM.

OUTCOMES

- Hughston and Jacobsen10 reported good functional results at 4 years in 12 of 19 patients treated with arcuate complex advancement combined with distal primary repair.
- DeLee et al8 also reported that 8 of 11 patients treated with advancement surgery had good results, with no arthritis or revisions at 7.5 years.
- Noyes and Barber-Westin22 reported on 42 months of follow-up in 21 patients treated with Achilles tendon allograft reconstruction of the LCL with plication or advancement of attenuated posterolateral structures.
- Failure occurred in 2 patients, and good to excellent functional results were reported in 16 (76%) patients.
- Lattimer et al19 reported on 10 patients treated with bone–patellar tendon–bone reconstruction of the LCL as well as cruciate ligament reconstruction at 28 months of follow-up.
  - All 10 patients had a reduction in their sensation of instability.
  - The patients all had less than 5 mm of lateral opening to varus stress and less than 5 degrees of external rotation.
  - Nine of the 10 patients returned to within one level of their preinjury level of activity.
- The long-term incidence of degenerative arthritis following PLC injuries treated with surgery remains unknown.
- No long-term prospective studies exist that evaluate the different ways to ligamentously reconstruct the knee with a PLC injury. Because this injury is uncommon, large study populations are difficult to obtain.

- Consequently, it is difficult to determine the clinically best method of treating this injury.

COMPLICATIONS

- Because of the extensive trauma usually incurred by the PLC-injured knee, arthrofibrosis is one of the most common complications associated with this injury.
- Residual knee instability also can occur, especially in grade 3 PLC injuries treated nonoperatively.
- These two conflicting complications make postoperative management as important as the surgical treatment itself for a good result.
- Neurovascular complications are more often associated with the initial trauma rather than the surgical management. Delayed surgical treatment increases the incidence of iatrogenic peroneal nerve injury, however.
- The incidence of wound complications can be decreased by delaying surgery until the skin has recovered from the acute phase of the injury, which usually is 10 days or more after the initial injury.
  - Bulky compressive dressings and elevation of the leg also may help decrease swelling before surgery.
  - Skin incisions should be planned to avoid skin bridges less than 7 cm wide.
  - The incidence of degenerative joint disease is increased in patients with PLC injuries due to abnormal joint motion.2,17
- The goal of surgical intervention is to reconstruct knee motion and stability to be as normal as possible.
- The lateral compartment and patellofemoral compartments are most commonly affected by PLC injuries.
- Because of long surgical times and use of graft material, infection is a possible complication of PLC surgery.
- Infection is a devastating complication, because to clear the infecting organism, it is often necessary to débride the grafts that were used to reconstruct the knee.

REFERENCES

DEFINITION

- Multiligament knee injuries result from both high-energy (eg, motor vehicle collisions) and low-energy (eg, athletic injuries, falls) events. Dislocation of the tibiofemoral joint is common, with or without spontaneous reduction.

ANATOMY

- Put very simply, knee dislocations can be viewed as injuries to one or both cruciate ligaments (ie, anterior cruciate ligament [ACL] or posterior cruciate ligament [PCL]), with variable involvement of the collateral ligaments (ie, the medial collateral ligament [MCL] and the fibular collateral ligament [FCL]) with important musculotendinous stabilizers—the biceps femoris and popliteus posterolaterally, and the pes anserine complex medially, all of which must be considered in restoring knee function. Palpable bony landmarks about the knee are crucial to aid in orientation for examination and when planning subsequent surgical approaches.

- The lateral femoral epicondyle and the fibular head are critical to identify the placement of lateral incisions, as are anatomic structures such as the FCL and peroneal nerve. Medially, the femoral epicondyle, tibial tubercle, pes insertion site, and posteromedial tibial edge are crucial landmarks for medial surgical exposures for inlay and MCL reconstruction.

- The intrinsic structure of the vascular system of the knee consists of an anastomotic ring of five geniculates: the superficial, superolateral, inferomedial, inferolateral, and middle geniculates, as well as muscular and articular branches.

- The extrinsic system plays a crucial role when parallel medial or lateral incisions are made about the knee in the sagittal plane.

- Proper planning should allow 7 to 10 cm between superficial parallel incisions to greatly lessen the risk of skin bridge loss, but it has been our experience that such incisions should be avoided if possible. This network alone cannot support vascularity distal to the knee with popliteal vessel occlusion.

- The surgical anatomy of the knee usually is described in layers, going from the superficial structures to the deep structures.

- Layer I is commonly described as consisting of Marshall’s layer (arciform) anteriorly, the sartorius medially, and the iliotibial band and biceps femoris fascia laterally.

- Layer II includes the FCL, patellar tendon, and superficial MCL.

- Layer III includes the posterior oblique, arcuate ligament, and deep portion of the MCL. Layer III is thin anteriorly and has distinct, structurally important thickenings posteromedially (posterior oblique ligament) and posterolaterally (arcuate ligament). A Segond fracture is caused by avulsion of the thickened middle third of the lateral knee capsule in this layer.

- Posterolateral reconstructions are complex because of this anatomy and variability and require restoration of both the FCL and popliteofibular (PFL) ligaments.

- The surgeon should understand the important anatomic relationships of the posterior structures of the knee, especially in regard to the popliteal neurovascular bundle.

- The medial and lateral heads of the gastrocnemius are the borders of the popliteal fossa distally, the pes anserinus tendons medially, and the biceps femoris tendon laterally. The popliteus, posterior joint capsule, oblique popliteal ligament, and posterior femoral cortex form the floor of the fossa. Through this fossa run the plantaris muscle and the neurovascular structures. The popliteal artery enters through the adductor magnus superiorly as it leaves Hunter’s canal, courses through the fossa, and exits through the soleal arch. The popliteal vein enters superficial to the artery and continues superficial to the artery, but is located deep to the tibial and common peroneal nerves, leaving the fossa medial to the popliteal artery.

- The vascular structures are located directly behind the posterior horns of the medial and lateral menisci. The vascular structures are protected during posteromedial and posterolateral approaches if the surgeon remains anterior to the medial and lateral heads of the gastrocnemius during dissection and careful retraction; of course, further dissection towards the midline can injure the bundle with either approach.

- With the advent of posterior procedures to the tibial side of the PCL, it is critical to understand the posterior neurovascular anatomy. The posteromedial approach also is useful to gain access to the tibial insertion of the PCL.

- Deep dissection along the posterior tibial surface and femoral condyles provides additional safety for this approach. Use of a tourniquet during dissection provides improved visualization of the surgical planes.

- Unlike the vascular surgeon, who uses a posteromedial approach for the neurovascular (popliteal) bundle, the orthopedic surgeon dissecting posteromedially should avoid the neurovascular bundle. Staying anterior to the medial gastrocnemius and hugging the posterior aspect of the knee joint protects the bundle in the orthopedic approach.

- It is important to stop the dissection at the PCL, because further dissection laterally with this approach eventually will reach and potentially injure the bundle.

NATURAL HISTORY

- Before the development of modern surgical techniques for management of multiligament injuries, scores of patients were left with stiff, unstable, or even amputated limbs. Today, even with aggressive evaluation and treatment, patients ultimately may have residual instability with a lower level of activity, decreased range of motion (ROM), and even amputation. The use of allografts in multiligament-injured knees is a recent advance, although occasionally it is complicated by deep infection.
PATIENT HISTORY AND PHYSICAL FINDINGS

- During the initial evaluation of a patient with a suspected multiligament knee injury, the clinician should be cognizant of the potential for concomitant injuries. High- or low-energy knee trauma can have potentially life- or limb-threatening injuries, which must be identified acutely.
- Once any life-threatening injuries have been treated, careful examination of the injured limb focuses both above and below the knee to evaluate for fracture as well as continuity of the extensor mechanism.
- A careful injury history should be obtained if possible, including pre-hospital neurovascular status of the limb, time of injury, and mechanism. Patients often relate a history of hyperextension of the knee in sporting events or a flexed knee that struck the dashboard during a motor vehicle accident.
- Any evidence of current dislocation of the tibiofemoral joint should be addressed emergently, with attempted reduction under sedation, splinting, careful neurovascular examination pre- and post-reduction, and high-quality radiographic evaluation following reduction.
- The radiographic evaluation should include an anteroposterior and lateral radiographs of the knee with the limb in a long-leg splint to demonstrate that a successful reduction has been achieved.
- Any asymmetry in the vascular examination from the uninjured extremity, even pre-hospital, necessitates further evaluation, with the specifics often dictated by vascular surgery protocols and regional preference.
- Many clinicians routinely obtain angiograms regardless of the vascular examination findings with multiligament injured knees. Nonetheless, the current trend toward using sequential clinical examinations in the reduced dislocation with normal pulses is becoming more popular and is considered safe.
- Use of Doppler or other noninvasive vascular laboratory studies in conjunction with an ankle brachial index is very useful, because these studies can provide objective information (rather than the subjective findings of pulses), and also avoids the invasiveness of angiography.
- The surgeon must be aggressive in the management of any abnormal vascular findings, with immediate vascular consultation and immediate surgical exploration of ischemia in the reduced knee dislocation. Ischemia in the dislocated knee requires reduction and pulse or vascularity reevaluation. Continued ischemia for more than 6 to 8 hours results in amputation rates of up to 80%.
- Medial puckering of the soft tissues of the knee usually suggests a posterolateral dislocation with buttonholing of the medial femoral condyle through the joint capsule, MCL incarceration into the joint, and irreducibility with closed methods of reduction.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- An integral part of evaluation of the multiligamentously injured knee is plain radiographs before and after reduction to confirm congruity of the joint, evaluate for associated fractures, and detect ligament avulsion injuries that may aid in timing of the treatment plan.
- MRI is an excellent adjunct to delineation of the extent of injury and pattern of ligament injury and musculotendinous and osteoarticular injuries. These studies are combined with a careful examination of the ligamentous structures with and without anesthesia, which are compared to the uninjured extremity.
- MRI cannot replace a careful clinical examination under anesthesia, which can determine ligament function and the need for ligament reconstruction.

CLASSIFICATION

- Multiple classification systems have been used to describe dislocations of the knee.
- Historically, the most commonly used system has been based on a positional description of the relationship of the femur on the tibia when the knee is dislocated. However, this system is not without problems.
- First, most knee dislocations present spontaneously reduced, making classification based on position at the time of injury difficult, if not impossible.
- Second, this system does not provide information regarding the energy of the injury, the ligaments injured, or associated neurovascular injuries, all of which play a part in the overall treatment plan.
- Classifying dislocations based on the anatomic injury pattern (ie, ligaments torn and associated neurovascular injuries) allows for adequate physician communication (especially for future reconstructions) and preoperative planning. The anatomic classification is shown in Table 1.

DIFFERENTIAL DIAGNOSIS

- Knee dislocations can be difficult to assess in the presence of gross knee swelling or with the presentation of multi-trauma.
- Accurate detection of associated neurovascular injuries is critical.
- Identification of the ligaments injured is based on the initial examination, imaging studies, and examination under anesthesia.

NONOPERATIVE MANAGEMENT

- Many patients today are treated with surgical management of some type; however, depending on their injury pattern,
there are still subsets that are treated nonoperatively. These include patients with severe comorbidities that increase the risks of surgery or those with open dislocations or greatly damaged soft tissue envelopes, where the focus is on restoring the envelope and treating infection.

**Cast Immobilization**
- Although cast immobilization technique was used for many years to treat multiligament injuries to the knee before modern reconstructive procedures were available, closed treatment as definitive management rarely is indicated.
- Immobilization in extension for 6 weeks, as described by Taylor,26 can result in a stable knee, but in our experience should be used only in circumstances where the preferred technique of ligamentous reconstruction is not applicable or feasible.

**External Fixation**
- External fixation may be used to span the knee joint with fixation in the tibia and femur, and is useful in patients who have poor rehabilitation potential. It also may be used as a temporary stabilizing measure in open knee dislocations, severe soft tissue injuries, and vascular reconstructions while awaiting optimal conditions for operative ligamentous reconstructions.
- Advantages include adequate maintenance of reduction, access to soft tissue wounds, and protection of maturing reverse saphenous vein grafts.
- However, the potentials for loss of knee motion and exuberant scar formation (arthrofibrosis) exist, and these often require later manipulation under anesthesia and lysis of adhesions.

**Hinged Knee Brace**
- The patient is placed in a hinged knee brace, and supervised ROM exercises are initiated in the first few weeks following the injury.
- This treatment method is ineffective in creating a stable knee but is an extremely important step in the process to a successful multiligamentous reconstruction.
- Gaining extension, a more normal gait pattern, full flexion, and decreased swelling (resolution of inflammation) add to an easier postoperative course, with avoidance of postoperative stiffness and heterotopic ossification with multiligamentous reconstruction. In our experience, early multiligamentous reconstruction has tremendous risks for stiffness and a poor result.
- The work of Shelbourne21 and others with ACL/MCL injuries with preoperative rehabilitation is even more applicable to multiligament knee injuries. Obtaining preoperative ROM before PCL, ACL, and collateral ligament reconstruction is extremely useful in obtaining a stable, pain-free knee after dislocation.

**SURGICAL MANAGEMENT**

**Indications**
- Operative reconstruction is recommended to most patients with multiligament knee injuries. In some cases, an external fixator is used temporarily followed by surgical reconstruction; in most cases, early braced knee motion is instituted with delay of reconstruction of ligament injuries undertaken only once motion is restored and inflammation is resolved.
- Ligamentous repair (ie, suture repair) is less and less commonly used, because the results are variable, and the use of early postoperative ROM, in our experience, results in failure of the suture repair.
- Crucial to the immediate care of these injuries is a meticulous neurovascular examination. Any vascular deficit necessitates emergent vascular surgery consultation and consideration for an open popliteal artery exploration and reverse saphenous vein graft reconstruction.
- Patients with open injuries, popliteal artery reconstructions, severe soft tissue injuries, or complex injury patterns (concomitant fractures) should be considered for external fixation for 2 to 4 weeks to allow healing of the soft tissue envelope and maturation of the arterial repair or reconstruction. Once conditions have been optimized and wounds are healed without infection, reconstruction can be performed.
- The optimal timing for surgical intervention is not clearly defined, although many investigators recommend waiting for several weeks after the injury before performing surgical repair or reconstruction of these multiligamentous injuries. The operating surgeon must have a good working knowledge of ligamentous reconstructions and should proceed according to his or her level of experience and preference.
- In our experiences, it is best to wait for preoperative motion, gait, and swelling to improve. Over 15 years of experience with knee dislocations has led to the following guidelines:
  - Delayed reconstruction is better than immediate surgery.
  - Preoperative rehabilitation is useful to regain motion, and resolution of swelling and inflammation is critical to surgical success.
  - Reconstruction is done with allo- and autografts, avoiding surgical repairs.
  - Both cruciates and involved collateral(s) are reconstructed simultaneously.

**Graft**

**Graft Choice**
- Many graft choices are available for ACL reconstruction in the multiligament-injured knee. We prefer a bone–patellar tendon–bone (BTB) allograft.
- While a BTB autograft is the gold standard in an isolated ACL reconstruction, the comorbidities of ipsilateral graft harvest in combined ACL-PCL injuries can result in stiffness, especially in simultaneous cruciate reconstruction.
- The ipsilateral hamstring autograft should not be considered in a type III knee dislocation (KDIII) injury, because the hamstrings provide a secondary restraint to valgus load and may be required for MCL reconstruction.
- Allografts are ideal for the multiligamentous knee injury.

**Posterior Cruciate Ligament Reconstruction**
- A number of approaches to modern PCL reconstruction are available, including (1) transtibial and femoral tunnels (with or without dual femoral socket) and (2) tibial inlay using a single or dual femoral tunnel in which tibial fixation is achieved by securing a bone plug into a trough positioned at the anatomic insertion of the PCL.
- The inlay technique places the bone–tendon junction of the graft at the joint line of the proximal tibia and may avoid the risk of the “killer curve” graft impingement seen experimentally with the transtibial tunnel technique.
- One of the senior authors prefers a dual femoral socket (ie, double-bundle femoral) and tibial inlay PCL reconstruction through a posteromedial approach.
BONE–PATELLAR TENDON GRAFT FOR BONE–ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

- The patient is positioned supine with a lateral post or leg holder in place.
- Standard arthroscopy portals are used, and a systematic examination of the knee is performed.
- Tibial and femoral tunnels 10 to 11 mm in diameter are drilled using standard methods.
- The allograft BTB bone plugs for the ACL are fashioned to match the tunnel diameter, and the femoral plug is fashioned to a length of 25 mm.
- A small drill is used to place a hole in the femoral bone plug of the graft and a no. 2 braided composite suture (Fiberwire, Arthrex, Naples, FL) is passed through the hole for graft passage.
- Two holes are drilled in the tibial bone plug and a no. 2 suture is passed to aid in graft passage, and even potential post or staple fixation in case of graft length mismatch.
- A critical step in planning the depth of the femoral tunnel is factoring in the length of the allograft.
  - The femoral tunnel should be drilled to a length of 30 to 35 mm.
  - Most patients require an intra-articular graft length of 25 mm.
  - Sixty millimeters (35 mm for the femoral tunnel plus 25 mm for the intra-articular portion) should be subtracted from the length of the entire graft to yield the ideal tibial tunnel length.
  - This method ensures that optimal fixation of the bone plug in the tibial tunnel will be possible.
  - A guide pin is placed endoscopically through the tibial tunnel into the femoral ACL origin and drilled out the anterolateral cortex of the femur and through the skin.
- A no. 2 braided composite suture from the femoral bone plug is placed through the eyelet of the guide pin.
- The guide pin and suture are pulled up into the femoral ACL socket, passing into the femoral tunnel.
- Fixation on the femoral side is performed using an interference screw through the inferomedial portal with a protective sleeve.
- Fixation and tensioning of the tibial side of the ACL graft are delayed until after PCL reconstruction.
- At this point, the PCL dual femoral socket sites are selected and drilled (discussed later in this section).
- Sutures are placed in the PCL femoral tunnels to allow graft passage.
- Once the PCL graft is securely fixed, then, and only then, is the ACL allograft tensioned in full extension and secured to the tibial tunnel using a metal interference screw.
- If graft tunnel mismatch occurs and the ACL tibial bone plug is not completely within the tibial tunnel, tibial interference fixation can be performed with an oversized soft tissue biodesgradable interference screw, or staple–post fixation can be performed externally on the tibial surface.
- In our experience, simultaneous bicruciate reconstruction, although complex, can be simplified by the following steps, performed in this order:
  - ACL femoral and tibial tunnel preparation; dual femoral PCL tunnel preparation; ACL graft passage with fixation of the femoral side only; tibial inlay via the posteromedial approach; PCL graft passage and fixation; ACL tibial fixation; and, lastly, collateral reconstruction as indicated.
  - Such steps allow for the most time-efficient process for simultaneous cruciate reconstruction.
DOUBLE-BUNDLE POSTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Positioning and Preparation
- The patient is positioned supine on the operating table with the use of a lateral post. A careful examination under anesthesia is performed to confirm the ligament injury and diagnosis.
- Standard inferomedial and inferolateral arthroscopy portals are used.
- A 30-degree arthroscope is inserted and diagnostic arthroscopy performed to confirm the PCL tear.
- The PCL remnant is removed and the anatomic origin identified.

Double-Bundle Tunnel Preparation
- A long drill-tip guidewire is placed through the inferolateral portal with the knee positioned at 90 degrees, viewing the pin placement from an inferomedial portal. This allows sequential femoral bundle pin placement and reaming for the anterolateral bundle of the PCL (8-mm tunnel) followed by posteros medial tunnel creation (6 mm).
- The guidewire is inserted in the anatomic site of the anterolateral bundle (usually high in the notch, near the articular surface), drilled into the condyle and exiting out of the skin overlying the distal medial thigh.
- The slotted end of the guidewire is used to pass a suture into the tunnel, with the loop remaining in the tunnel.
- At our institution, both tunnels are reamed endoscopically through the medial cortex to allow for adequate graft tensioning.
- At this point, both femoral sockets have been reamed, passing sutures are in place (exiting the inferomedial portal), and the posteros medial approach is performed.

Posteromedial Approach and Tibial Inlay Site Preparation
- All arthroscopic instruments are removed from the knee, and the leg is placed in the figure 4 position.
- The primary surgeon is positioned on the contralateral side of the operating table with the assistant on the ipsilateral side of the injured knee.
- The leg is exsanguinated, and the tourniquet is inflated with the knee hyperflexed.
- A posteromedial approach to the knee is utilized, with a 6- to 10-cm incision centered over the posterior joint line. The incision should follow the posterior cortex of the proximal tibia and the medial femoral epicondyle.
- The sartorius fascia is exposed and incised in line with the skin incision. The gracilis and semitendinosus tendons are retracted posteriorly and distally. The fascia between the medial head of the gastrocnemius muscle and the posterior border of the semimembranosus muscle is divided in line with the incision. The semimembranosus muscle is then dissected off of its tibial insertion and tagged with a nonabsorbable suture for later repair.
- The remainder of the exposure is performed by blunt dissection following the posterior border of the joint line and remaining anterior to the medial head of the gastrocnemius muscle at all times to protect the popliteal neurovascular structures.

Graft Preparation
- As noted earlier, our preferred graft for PCL reconstruction is an Achilles tendon allograft.
- This graft allows for either a single- or double-bundle femoral technique, depending on surgeon preference and experience.
- The graft can easily be fashioned into a double-bundle graft.
- The ends are prepared by placing a traction stitch with a no. 2 Fiberwire suture to facilitate graft tubulization and eventual passage.
- The calcaneal bone plug is fashioned to maintain the double-bundle tendons and can vary in size (often, it is 15 mm wide × 15 mm deep × 35 mm long). Hence, graft preparation must be performed before tibial trough creation.

Tibial Graft Passage and Fixation
- The tibial inlay graft is positioned into the tibial trough with care taken to ensure that the bone–tendon junction is positioned at the joint line.
- The tibial side of the graft is fixed first to ensure that the bone–tendon junction is positioned at the joint line to avoid graft abrasion.
The key components of the deep posterolateral corner are the popliteus, the PFL, and the FCL. The modified two-tailed reconstruction\(^\text{16}\) addresses each of these components.

### SINGLE-LOOP POSTEROMEDIAL COMPLEX RECONSTRUCTION

- An incision is made from the medial femoral epicondyle to the posterior aspect of the insertion of the pes anserinus tendon on the tibia. The sartorius fascia is incised in line with the semitendinosus tendon from distal to proximal, and graft harvest is performed, leaving the tibial attachment in place.
- The proximal end of the semitendinosus is cleared of remaining muscle, and a Krackow suture is placed in its free end.
- A subretinacular tunnel is made from distal to proximal, and the graft is passed using this approach.
- Using a high-speed burr, a U-shaped trough is made around the isometric point of the medial epicondyle.
- The graft is laid into this trough and stapled in place.
- The graft is passed back through the fascial tunnel, and the knee is cycled through a ROM.
- The graft is then stapled to the tibia at the insertion of the MCL.
- After wound closure, the limb is placed in a sterile bulky dressing with medial and lateral plaster slabs for 7 to 10 days.
- We monitor these patients carefully and progress them slowly through ROM.

### MODIFIED TWO-TAILED RECONSTRUCTION OF THE POSTEROLATERAL CORNER

- The patient is positioned supine on the operating table, with the injured extremity draped free. The leg is carefully positioned on the operative table, with the foot resting in the seated surgeon’s lap.
The knee is flexed to 90 degrees to relax the peroneal nerve, and a skin incision is made beginning at the lateral epicondyle of the femur toward the fibular head.

The iliotibial band is incised in line with the fibers from Gerdy’s tubercle, extending proximally to the supracondylar process of the femur.

At this point, the peroneal nerve is identified as it courses from the biceps femoris through the perineural fat to the fibular neck.

In our experience, the nerve is identified most easily at the level of the joint line, where it can be palpated. However, depending on the specific injury and the presence of inflammation, the nerve may be identified along the fibular neck or even as it crosses the lateral gastrocnemius head.

It is critical to identify the nerve first before any ligamentous exploration or reconstruction is performed.

Neurolysis is performed distally through the length of the incision. The nerve is protected with a small vessel loop.

Once the nerve is exposed and protected, the FCL and the posterolateral structures are identified through blunt dissection. The surgeon should not dissect posterior to the lateral gastrocnemius muscle, because this places the popliteal neurovascular structures at risk.

Once the exposure is complete, a 5-mm tunnel is drilled from anterior to posterior on the lateral tibia, exiting where the popliteus tendon traverses the back of the tibia.

A retractor is placed posteriorly during the drilling to protect the neurovascular structures.

The tibial tunnel is tapped with a 7-mm tap to allow fixation with a bioabsorbable interference screw.

A tibialis tendon allograft is fashioned to approximately 5 mm and passed into the tunnel from posterior to anterior.

The allograft tendon must be at least 24 cm long to allow reconstruction of all three components.

The graft is secured in the tibial tunnel with a 7-mm bioabsorbable interference screw from anterior to posterior.

A second 5-mm tunnel is made in the fibular head from anterolateral to posteromedial, but is not tapped.

The isometric point on the lateral femoral condyle is located by finding the intersection of the FCL and the popliteus tendon.

Using a 3.2-mm drill bit, a hole is made in the lateral femoral condyle at the isometric point from lateral to medial to allow placement of a 4.5-mm bicortical screw.

If a concomitant ACL reconstruction is performed, this hole must be drilled from posterior to anterior to avoid interfering with the femoral tunnel of the ACL graft.

An osteotome is used to decorticate the bone around the screw to allow healing of the allograft to bone. A spiked soft tissue washer is used with the screw.

The graft is then passed from the posterior aspect of the tibia to the anterior portion of the screw and then posteriorly around to the fibular tunnel.

The popliteofibular portion of the graft should lie deep to the popliteus portion of the graft.

The graft is then passed from posterior to anterior through the fibular tunnel and back to the screw and washer.

The graft is tensioned with the foot internally rotated and the knee flexed 40 to 60 degrees.

The screw and washer are then secured to the lateral femoral condyle and graft.

This completes the reconstruction of all three posterolateral components described earlier. If there is an injury to the PLC, early repair should be considered.

We prefer allografts for cruciate reconstructions performed simultaneously, but the decision is based on surgeon experience, patient preference, and risk tolerance.

Our graft of choice for bicruciate injuries is BTB allograft for the ACL and an Achilles tendon allograft for the PCL (dual-bundle femoral with inlay tibial bone plug).

The patient is positioned supine with the injured extremity draped free. A post is used to assist with arthroscopy.

Diagnostic arthroscopy is performed through standard portals, and associated injuries are treated as required.

The remnants of the cruciate ligaments are debrided, and a notchplasty is performed to allow for adequate visualization of ACL femoral tunnel placement and graft passage.

The detailed technique for ACL and PCL reconstructions is described earlier in this chapter.

The ACL tibial and femoral tunnels are prepared first, and the guide pin advanced into the femoral tunnel to be used later for graft passage. The femoral tunnel may be drilled under dry visualization.

The PCL femoral tunnel(s), either double-socket (preferred) or single, are prepared next under dry visualization. The guide pin is advanced into the femoral tunnel and the attached suture brought through the inferomedial portal for later graft passage.

Knee Dislocation Type II: Anterior and Posterior Cruciate Ligaments Torn

The integrity of the collateral ligaments allows for early ROM and a delayed reconstruction of the cruciate ligaments.

Knee Dislocation Type I: Anterior Cruciate and Collateral Ligaments Torn

The integrity of the ACL determines the timing of reconstruction for a type I knee dislocation.

ACL reconstruction is best delayed until ROM is restored, for two reasons:

- Collateral ligament healing usually occurs nonoperatively.
- Postoperative stiffness often is avoided.

We prefer to regain complete ROM and delay reconstruction for this type of injury. Patients usually regain knee motion within 6 weeks of the injury.

Graft choice is based on surgeon experience and patient preference and usually involves an ipsilateral bone–tendon–bone autograft.

Collateral ligament injury associated with only one torn cruciate ligament usually can be treated nonoperatively.

MULTILIGAMENT RECONSTRUCTIONS
PEARLS AND PITFALLS

### Neurovascular status
- Carefully evaluate pulses and the neurologic examination. Use noninvasive studies to objectively document the findings of a normal vascular examination. Aggressively (emergently) evaluate asymmetry or ischemia on vascular examination with vascular consultation and intraoperative arteriography/exploration.

### Planning
- Determine the impact of ligamentous reconstructions on the patient as a whole. Delay reconstructions for multi-trauma, and consider external fixation for such patients to assist in transfers and mobilization.
- Obtain preoperative ROM with normalized gait prior to reconstruction. This will maximize the final result. The PCL often will heal to a grade I or II, thereby making it possible to perform only an ACL/collateral reconstruction.
- Use allografts over autografts, depending on patient preference and religious beliefs.

### Diagnosis
- Clearly diagnose the ligaments involved. Examination under anesthesia combined with MRI can give an accurate picture of the needed reconstructions. Remember, MRI may overdiagnose ligamentous injuries, which will be found on EUA not to need reconstruction.

### Surgery
- Use reconstructions over repairs. If using repairs, delay postoperative ROM.
- Perform bicruciate and collateral reconstructions at the same sitting (simultaneously), if possible.

---

**Knee Dislocation Type III: Torn Anterior and Posterior Cruciate Ligaments and Lateral Complex**
- As for the Type III reconstruction, the reconstruction of a Type III injury proceeds through double-bundle passage into the dual femoral sockets.
- After the PCL is tensioned, the lateral approach to the knee is performed, and the FCL and posterolateral corner reconstructed using the technique described earlier.
- The ACL graft is then tensioned in extension and secured to the tibia.

**Knee Dislocation Type IV: Torn ACL, PCL, MCL, and Lateral Complex**
- This pattern most often is associated with a high-energy injury and represents a complex reconstruction.
- Careful attention to knee position during tensioning of the grafts is required to achieve a stable and concentric reconstruction in which the tibiofemoral joint is not subluxed.
- The initial reconstruction follows bicruciate ligament reconstruction through double-bundle passage into the dual femoral sockets, including exposure of the MCL.
- A lateral approach is used to expose the posterolateral corner, as described earlier.
- The MCL and PLC are prepared.
- The MCL graft is tensioned and fixed.
- The posterolateral graft is tensioned and fixed.
- The ACL graft is tensioned in extension and fixed to the tibia.
POSTOPERATIVE MANAGEMENT

- A thorough understanding of the reconstruction and tailoring the treatment plan to each individual patient are crucial to all rehabilitation protocols.
- Patients who undergo early repair or reconstruction of multiligament knee injuries should begin supervised knee motion exercises within the first 3 days after surgery to decrease the risk of arthrofibrosis.
- A hinged knee brace is used after bicruciate reconstructions, with non-weight bearing of the extremity recommended for 3 to 4 weeks.
- Weight bearing is progressed to full, usually at 6 weeks, with a brace and crutches.
- With medial or lateral procedures consideration is given for a slower return to full weight bearing owing to poor quadriceps tone and potential unfavorable mechanics.
- Early postoperative therapy focuses on control of edema and pain to facilitate return of quadriceps function.
- Following PCL reconstruction, early return of full extension is paramount.
- Supervised passive extension exercises are performed with a simultaneous, anteriorly directed force on the proximal tibia twice daily.
- The knee is kept in a postoperative brace from 0 to 90 degrees for the first 6 weeks.
- Closed kinetic chain active exercises are allowed in this arc of motion.
- The goal is to regain full ROM by 3 months.
- If 90 degrees of flexion is not achieved by 6 to 12 weeks, manipulation under anesthesia (MUA) is strongly recommended.
- Straight-line jogging usually is begun at 5 to 6 months, depending on quadriceps function.
- Patients may return to full activity in 9 to 12 months.

OUTCOMES

- The trend in recent years of increased surgical management of ligamentous injuries, coupled with earlier motion and a more aggressive approach to the management of stiffness (eg, MUA, arthroscopic lysis of adhesions), has yielded more favorable results than those previously reported regarding function, pain, and the incidence of debilitating instability.
- Studies using Lysholm scores for outcomes favor surgical treatment of these injuries over nonoperative treatment, with an average increase of 20 points reported with operative intervention.
- Generally speaking, 93% of patients are able to return to some type of occupation, but may not be able to work at a highly demanding job. In seven studies, approximately 70% of patients returned to their previous occupation.
- With surgical intervention, many patients ultimately have knees that function well for activities of daily living, and some are able to participate in recreational sports, but only 40% are able to return to their previous level of activity.

COMPLICATIONS

- One of the most devastating problems encountered in multiligament knee injuries is failure to identify and appropriately manage vascular injuries in the acute phase.
- Another common problem is failure to recognize the full extent of the ligamentous injury, including capsular disruption at the time of surgical management.
- There also is potential for nerve injury, with peroneal nerve involvement more common than tibial nerve injury.
- Complete nerve dysfunction carries a much worse prognosis than a partial injury, especially regarding the tibial nerve. Fewer than half of these patients have complete functional recovery of the nerve.
- The necessity of creating multiple femoral and tibial tunnels brings with it the potential risk of tibial plateau fracture, medial femoral condyle avascular necrosis, and subchondral fracture.
- The potential also exists for intraoperative neurovascular injury, especially with lateral side reconstructions (peroneal nerve) and PCL reconstructions (popliteal neurovascular bundle).
- Postoperatively, the risks include infection (especially with open injuries), wound healing problems with multiple incisions, and arthrofibrosis (with or without heterotopic ossification).
- On average, 38% of multiligament knee injuries require at least one surgical intervention to regain motion.
- There also is concern for posttraumatic arthritis (especially of the patellofemoral joint), potential loss of graft or repair fixation, and deep venous thrombosis with pulmonary embolus.

REFERENCES

Chapter 47 MANAGEMENT OF THE MULTIPLE LIGAMENT-INJURED KNEE

DEFINITION
- Complete tears of the patella tendon are best classified into acute versus chronic.
- Partial tears often can be managed nonoperatively. The functional integrity of the extensor mechanism is the key to determining the need for surgical repair.
- This chapter focuses on the surgical treatment of complete tendon disruption.

ANATOMY
- The patella tendon is approximately 30 mm wide × 50 mm long, with a thickness of 5 to 7 mm.¹
- The origin on the inferior pole of the patella is juxtaposed to the articular cartilage on the deep side and becomes confluent with the periosteum of the patella anteriorly.²
- The tibial insertion is narrower and invests the entirety of the tibial tubercle.
- The overlying peritenon is thought to be the cellular source for healing of tendon injuries.

PATHOGENESIS
- Tendon rupture usually is the result of underlying tendinosis.⁶
- There is some evidence of genetic predisposition to tendon rupture.
- Certain conditions predispose individuals to tendon rupture, including renal dialysis, chronic corticosteroid use, fluoroquinolone antibiotics, and corticosteroid use.

NATURAL HISTORY
- The natural history of an untreated patella tendon is complete extensor mechanism dysfunction.
- Untreated acute ruptures result in chronic lesions that are more difficult to manage surgically. These often require reconstructive procedures and have inferior functional results.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with acute tendon tears may report an audible “pop” or the sensation of their knee giving way.
- Patients with chronic injuries may report ambulatory difficulty and pain. These injuries often are treated with bracing before definitive evaluation.
- The loss of active knee extension is the key physical examination finding when evaluating for patella tendon rupture.
- Loss of tension in the patella tendon with the knee at 90 degrees of flexion and patella alta are indirect signs of rupture.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs may reveal patella alta, avulsion fractures, Osgood-Schlatter lesions, or other concomitant knee injuries.
- MRI scans may be helpful in determining the exact location of the rupture and evaluating concomitant intraarticular knee lesions.

DIFFERENTIAL DIAGNOSIS
- Quadriceps tendon rupture
- Patella fracture
- Tibial tubercle avulsion fracture

NONOPERATIVE MANAGEMENT
- Nonoperative management should be considered only for patients who are not surgical candidates because of medical comorbidities.

SURGICAL MANAGEMENT
- Although not considered to be a surgical emergency, prompt surgical management of acute patella tendon ruptures is recommended.

Preoperative Planning
- Repairs of chronic injuries often require allograft tissue availability and careful surgical planning.
- Significant patella alta may require proximal release in conjunction with the repair.

Positioning
- Supine positioning is recommended.
- Use of a tourniquet may preclude proper repair tensioning in chronic injuries.
- Prepping and draping of both lower extremities allows use of contralateral limb as a template for patella positioning.

Approach
- An anterior approach is used, regardless of the repair technique.
- A midline longitudinal incision is made over the patella tendon.
- The peritenon is incised longitudinally and dissected away from the underlying tendon.
ACUTE REPAIR

Midsubstance
- Grossly pathologic tendon tissue is aggressively débrided.
- The full length of the patella tendon is exposed.
- Two Krackow locking stitches are placed in each tendon stump with no. 2 or no. 5 Fiberwire (Arthrex, Inc., Naples FL; TECH FIG 1).
- Any required retinacular repair stitches are placed with absorbable suture before the tendon repair.
- The four proximal core sutures are tied to the four distal core sutures with the knee in full extension.
- Integrity of the repair is evaluated by checking the maximal flexion possible prior to gap formation.
- The peritenon is closed with absorbable suture.

Proximal Avulsion
- Grossly pathologic tendon or bone is removed.
- Exposure of the inferior pole of the patella is performed.
- If the transosseous drill hole technique is preferred, superficial exposure of the superior pole of the patella is required.
  - A smaller exposure is required for suture anchor technique.
- Three suture anchors are placed in the inferior pole of the patella, equally spaced along the anatomic tendon footprint.
  - We prefer the 5.0 Bio-Corkscrew FT Suture Anchor (Arthrex, Inc., Naples, FL) loaded with no. 2 Fiberwire (Arthrex, Inc., Naples, FL).

Distal Avulsion
- Grossly pathologic tendon or bone is removed.
- The tibial tubercle is exposed.
- Two suture anchors are placed in the tibial tubercle.
  - We prefer the 5.0 Biocorkscrew FT Anchor loaded with no. 2 Fiberwire (Arthrex, Inc., Naples, FL).
- The suture is pulled through the anchor eyelet to produce long and short suture arms. The long suture arm is passed down and back up the tendon stump in a locking Krackow fashion (TECH FIG 2).
- The tendon is manually reduced to the inferior pole of the patella, and the slack is taken out by the short arm of suture pulled through the eyelet.
- Each suture pair is tied securely to complete the repair.
- Repair integrity is evaluated by checking the maximal flexion possible before gap formation.
- The peritenon is closed with absorbable suture.

The suture is pulled through the anchor eyelet to produce long and short suture arms.
- The long suture arm is passed down and back up the tendon stump in a locking Krackow fashion (TECH FIG 2).
- The tendon is manually reduced to the inferior pole of the patella, and the slack is taken out by the short arm of suture pulled through the eyelet.
- Each suture pair is tied securely to complete the repair.
- Repair integrity is evaluated by checking maximal flexion possible before gap formation.
- The peritenon is closed with absorbable suture.
**TECH FIG 3** • Repair of acute distal avulsion.

- The block is secured to the tubercle with 2-mm × 3.5-mm cortical screws (TECH FIG 4A).
- Suture anchors are placed into the distal pole of the patella and onto the anterior cortex of the patella to secure allograft tendon to the patella (TECH FIG 4B).
- The allograft tendon is draped over the quadriceps tendon and muscle fascia and secured with nonabsorbable suture.

**RECONSTRUCTION OF CHRONIC TEARS**

- Reconstruction of a chronic tear begins with aggressive débridement of dysplastic tissue.
- Remaining tendon tissue is assessed for possible repair.
- The tibial tubercle is exposed.
- The Achilles allograft is prepared with 15-mm × 25-mm bone block.
- A rectangular box is cut out of the tubercle with an oscillating microsurgical saw and osteotomes to receive the bone block.
- The block is secured to the tubercle with 2-mm × 3.5-mm cortical screws (TECH FIG 4A).
- Suture anchors are placed into the distal pole of the patella and onto the anterior cortex of the patella to secure allograft tendon to the patella (TECH FIG 4B).
- The allograft tendon is draped over the quadriceps tendon and muscle fascia and secured with nonabsorbable suture.

**TECH FIG 4** • Chronic reconstruction with Achilles tendon allograft. The bone block is inlayed into the tibial tubercle and fixed with screws or staples. The soft tissue end of the graft is sutured into the patella with suture anchors and into the quadriceps with heavy nonabsorbable sutures. **A.** Lateral view. **B.** AP view.
AUGMENTATION PROCEDURES

- After the repair has been completed, it is assessed for any need for augmentation.
- The following materials can be used for augmentation. They are placed in a box-stitch fashion through drill holes in the patella and tubercle (TECH FIG 5A):
  - Mersilene tape
  - No. 5 Fiberwire
  - No. 5 Ethibond
  - Steel wire
  - Cerclage cables
  - Tibialis tendon allograft
  - A semitendinosus autograft also may be harvested proximally (while leaving its distal insertion intact) and passed through a drill hole in the patella and either through a drill hole in the tubercle or potted into the proximal tibia if the length is insufficient (TECH FIG 5B).

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Preoperative planning</th>
<th>Failure to recognize significant patella alta may lead to abnormal knee kinematics and weakness of extension.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Surgical technique</td>
<td>Reattachment of the patella tendon into its anatomic footprint on the patella is essential for re-establishing normal patellofemoral kinematics.</td>
</tr>
<tr>
<td>Intraoperative assessment</td>
<td>Maximum allowed knee flexion angle without repair gap formation is determined immediately after repair.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Weight bearing is allowed with the knee braced in extension.
- Early flexion allowances are determined intraoperatively by the quality of the tendon tissue and repair.
- Active-assisted range of motion is advanced as tolerated with the goal of 90 degrees of flexion by 4 to 6 weeks and full motion by 10 to 12 weeks after repair.
- Strengthening is initiated immediately with isometric quadriceps contractions and progressed to straight-leg raises at 6 weeks.
- Return to unrestricted activities is delayed until 6 months.

OUTCOMES

- Marder and Timmerman\(^9\) reported excellent results in 12 of 14 patients treated with acute repair without augmentation.
- Larson and Simonian\(^7\) reported excellent results (mean Lysholm score, 97.5) in four cases of acute repair augmented with autologous semitendinosus graft placed in a looped fashion.
- Lindy et al\(^8\) reported excellent results in 24 patients repaired acutely and augmented with Mersilene tape placed in a looped configuration.
- Fujikawa\(^5\) reported good results with a patella tendon repair augmented with a synthetic figure-8 weave performed on six
patella tendon ruptures. They noted that the augmentation device allowed for early mobilization and good functional outcome.

- Two recent biomechanical studies show that an augmented repair is stronger than an unaugmented repair and that suture anchor repair is at least as strong as repair through drill holes.
- Two cases of successful treatment of chronic patella tendon ruptures with Achilles allograft reconstruction have been reported.

COMPLICATIONS

- Rerupture is the most worrisome complication.
- Infection is uncommon but devastating.
- Residual quadriceps weakness and extensor lag are more common with repairs of chronic injuries.

REFERENCES

DEFINITION

- Quadriceps tendon ruptures result in disruption of the fibers of this tendon, thereby disrupting the extensor mechanism of the knee.
- Injury is prevalent in patients more than 40 years old and is more common in men.
- Ruptures usually occur transversely through the tendon at a pathologic area approximately 2 cm proximal to the superior pole of the patella, and then progress obliquely into the medial and lateral retinacula based on the amount and duration of force.
- Ruptures can occur at the bone–tendon interface (older patients), or at the midtendinous or musculotendinous area (younger patients).9
- Unilateral ruptures are more common; bilateral ruptures may occur because of a predisposition from an underlying systemic condition.
- Acute repair of the tendon provides a higher rate of return of function.

ANATOMY

- The quadriceps tendon consists of the coalescence of the rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius, about 3 to 5 cm proximal to the patella, and inserts into the superior pole of the patella.
- The quadriceps tendon averages 8 mm in thickness and 35 mm in width.11
- Normal quadriceps tendon layers include three layers:
  - Superficial layer, which originates from the posterior fascia of the rectus femoris
  - Deep layer, which originates from the anterior fascia of the vastus intermedius
  - Middle layer, which originates from the deep fascia separating the vastus medialis and lateralis from the vastus intermedius.11
- The tendon receives its blood supply from multiple contributions: branches of the lateral circumflex femoral artery, the descending geniculate artery, and the medial and lateral superior geniculate arteries.8
- The distribution of the blood supply in the tendon is asymmetric8:
  - The superficial tendon vascular supply is complete from the musculotendinous junction to the patella.
  - The deep portion of the tendon has an oval avascular area.

PATHOGENESIS

- Quadriceps tendon rupture typically occurs through a site of pathologic degeneration in the tendon caused by repetitive microtrauma.4,5
- Rupture is the result of eccentric contraction of the extensor mechanism against a sudden load of body weight with the foot planted and the knee flexed.7
- Rupture can be due to trauma, use of corticosteroids, and systemic diseases (eg, gout, pseudogout, systemic lupus erythematosus, renal failure, hyperparathyroidism, diabetes mellitus).2
- Fluoroquinolone antibiotics (eg, ciprofloxacin) also have contributed to tendon weakness.
- Bilateral ruptures typically are the result of systemic medical conditions.

NATURAL HISTORY

- Unrepaired quadriceps tendon rupture can lead to chronic extensor lag and weakness.
- Long-term rupture may lead to quadriceps fibrosis as well as patella baja.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Immediate pain, occasional swelling, subcutaneous hematoma
- Occasionally hears or feels a “pop”
- Inability to bear weight
- Pre-existing pain and symptoms related to quadriceps tendon (tendinitis) prior to injury
- Effusion can be indicative of hemarthrosis.
- Loss of extension (straight leg raise) indicates lack of continuity of the extensor mechanism (note: ability to extend may be due to intact retinacula).
- Suprapatella gap (ie, soft tissue defect proximal to the superior pole of the patella) is indicated by loss of continuity of the extensor mechanism at the quadriceps tendon attachment.
- Patella baja (ie, patella of the injured knee more inferior than the contralateral knee) is indicated by loss of proximal extensor mechanism.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs (especially lateral view) may demonstrate bony avulsion fractures at the superior patella or soft tissue calcific deposits in chronic tendinosis.
- Tooth sign$: on Merchant’s view, vertical ridging of osteophytes at the quadriceps tendon attachment site
- Ultrasound, while operator dependent and not as specific, may demonstrate a discrete break in the tendon with abnormal overlying soft tissue.
- Arthrography is invasive; however, it is positive with extravasation of contrast dye from the suprapatellar pouch and along the tendon sheath of the tendon.1
- MRI remains the gold standard in diagnosing partial and complete quadriceps tendon ruptures, in addition to associated soft tissue injuries.
- Notable findings include focal tendon discontinuity, increased signal in the tendon, wavy patella tendon, as well as possible pre-existing pathology.
DIFFERENTIAL DIAGNOSIS
- Patella tendon rupture
- Quadriceps tendon rupture
- Patella femoral contusion
- Cartilage contusion
- Neural injury

NONOPERATIVE MANAGEMENT
- Patients with partial quadriceps tear may be treated non-operatively.
- For the first 6 weeks, the knee is immobilized in extension to assist with tendon healing and maintenance of tendon length.
  - This can be done with a long-leg brace locked in extension or with a long-leg cylinder cast.
  - Patients should be non-weight bearing with crutches.
- In the first 6 weeks, the patient may begin isometric straight leg raises.
- In the next phase, regaining flexion is emphasized and the brace is unlocked to allow restoration of normal gait.
  - The patient is advanced to full weight bearing.
- In the last phase, strengthening is emphasized.
- Patients can return to activity once full range of motion and strength are restored, usually in 4 months.

SURGICAL MANAGEMENT
- All complete tendon ruptures should be repaired acutely to restore extensor function.
- Any partial rupture that has progressed to a complete rupture should also be repaired as soon as diagnosed.

PREOPERATIVE PLANNING
- Review all imaging studies.

ACUTE TENDON REPAIR AT THE TENDON–BONE INTERFACE

Tendon Preparation
- A straight 10-cm midline incision is made, centered over the bone–tendon interface.
- The superficial layers are retracted to examine the deep tissue layers (TECH FIG 1A).
- Hematoma is irrigated.
- The medial and lateral retinaculae are evaluated (TECH FIG 1B).
- The tendon edge of necrotic and degenerative tissue is débrided to normal-appearing healthy tendon tissue (TECH FIG 1C,D).
- Ability to reapproximate tendon ends without undue tension (TECH FIG 1E,F) is confirmed.

Suturing
- Using no. 2 or no. 5 nonabsorbable suture, beginning near the lateral free edge of the tendon, a continuous running-type stitch (eg, Krackow stitch, Mason-Allen stitch) is placed, exiting back at the free end of the tendon (TECH FIG 2A).
- This is repeated for the medial aspect of the tendon.
- When completed, there should be four equal strands of sutures exiting the free tendon edge (TECH FIG 2B,C).
- A trough is made at the superior pole of the patella to assist with tendon reattachment. The trough should not be placed too anteriorly, to avoid patellar tilt.
- Three longitudinal drill holes, 1 to 1.5 cm apart, are placed, exiting out of the inferior pole of the patella.
- Using a suture passer, beginning at the inferior pole of the patella, each of the four strands of suture is brought longitudinally through the patella (TECH FIG 2D,E).
- Holding the sutures provisionally, knee flexion is evaluated with patellar tracking and rotation.
- The tendon is reduced to the superior pole of the patella, and the sutures are tied with the knee in full extension (TECH FIG 2F).
- Knots are buried behind the patellar tendon at the inferior pole.
- To complete the repair, no. 0 nonabsorbable sutures are used in interrupted fashion to repair the medial and lateral retinacula (TECH FIG 2G).
- Patellar positioning, tracking, and tensioning of the repaired tendon are evaluated.
- The position of knee flexion at which tension begins on the repair should be noted, because this will determine the amount of maximum knee flexion allowed in postoperative rehabilitation.
Chapter 49  REPAIR OF ACUTE AND CHRONIC QUADRICEPS TENDON RUPTURES

TECH FIG 1 • Evaluating the deep tissue layers (A) and the medial and lateral retinacula (B). C. Patella retracted inferiorly, demonstrating tear. D. Alice clamps on quadriceps tendon demonstrating mobility of soft tissue. E. Reapproximating the quadriceps tendon to the patella. F. Confirmation that there is no excess tension on reapproximation for tendon repair.

TECH FIG 2 • A. Placement of a continuous running stitch, beginning laterally and exiting back at the free edge of the tendon. B. Four sutures exiting the free edge of the quadriceps tendon. C. Close-up of the four exiting sutures. D. Four sutures from the free edge of the quadriceps tendon brought inferiorly through three longitudinal drill holes in the patella. (continued)
A straight 10-cm midline incision is made centered over the bone–tendon interface. 
- Hematoma is irrigated.
- The tendon edge of necrotic and degenerative tissue is débrided down to normal-appearing healthy tendon tissue.
- Ability to reapproximate tendon ends without undue tension (see Tech Fig 1E,F) is confirmed.
- No. 2 or no. 5 nonabsorbable sutures are used for a continuous running stitch to reapproximate both proximal and distal free lateral edges of the tendon (TECH FIG 3A).
- Procedure is repeated for the proximal and distal medial edges of the tendon.

Tendon edges are reapproximated by provisionally tensioning sutures together and evaluating knee flexion with patellar tracking and rotation.
- The sutures are tied together with the knee in full extension, making sure not to overtension or overlap the reattachment (TECH FIG 3B).
- No. 0 nonabsorbable suture is used, if necessary, to reinforce repair with interrupted figure 8 stitches.
- To complete the repair, no. 0 nonabsorbable suture is used in interrupted fashion to repair the medial and lateral retinacula.
- Patellar positioning, tracking, and tensioning of the repaired tendon are evaluated.
- The position of knee flexion at which tension on the repair begins should be noted, because this will determine the amount of maximum knee flexion allowed in postoperative rehabilitation.

ACUTE TENDON REPAIR AT MUSCULOTENDINOUS AND MIDTENDINOUS AREAS

- A straight 10-cm midline incision is made centered over the bone–tendon interface.
- Hematoma is irrigated.
- The tendon edge of necrotic and degenerative tissue is débrided down to normal-appearing healthy tendon tissue.
- Ability to reapproximate tendon ends without undue tension (see Tech Fig 1E,F) is confirmed.
- No. 2 or no. 5 nonabsorbable sutures are used for a continuous running stitch to reapproximate both proximal and distal free lateral edges of the tendon (TECH FIG 3A).
- Procedure is repeated for the proximal and distal medial edges of the tendon.

TECH FIG 2 • (continued)  
E. The center two sutures exit through a central drill hole. F. Sutures are secured with their continuous loop mate—first the lateral set, followed by the medial set. G. Repair of lateral and medial retinacula.

TECH FIG 3 • A. Placement of two sets of continuous running stitches laterally and medially in both the proximal and distal stumps. B. Alignment of four exiting proximal and distal sutures that makes it possible to secure them to each other as tension is applied on the untied suture sets.
**CHRONIC TENDON REPAIR**

- Chronic ruptures have scar tissue present in addition to shortening.
- A longitudinal midline incision is used.
- The tendon is mobilized by releasing adhesions to the surrounding soft tissues, skin, and underlying femur.
- The tendon edges are débrided down to healthy tissue, and scar tissue is removed from the tendon gap.
- If the tendon can be reaproximated, it is repaired similarly to an acute repair.
- If the tendon cannot be apposed without undue tension, a reinforcement (Scuderi technique) or lengthening (Codivilla technique) procedure is indicated.

**Scuderi Technique**

- The tendon edges are débrided to healthy tissue, and scar tissue is removed from the tendon gap (TECH FIG 4A).
- The quadriceps edges are reapproximated and repaired together with interrupted no. 0 nonabsorbable sutures (TECH FIG 4B).
- An inverted V is incised through the full thickness of the proximal quadriceps tendon, with the base of the V ending approximately 1 cm proximal to the rupture (TECH FIG 4C).
- The apex of the V is folded distally and sutured in place (TECH FIG 4D).

This technique also can be used for acute repairs.10

**Codivilla Technique**

- The tendon edges are débrided to healthy tissue, and scar tissue is removed from the tendon gap (TECH FIG 5A).
- The quadriceps edges are apposed and repaired together with interrupted no. 0 nonabsorbable sutures (TECH FIG 5B).
- An inverted V is incised through the full thickness of the proximal quadriceps tendon, with the base of the V ending approximately 1 cm proximal to the rupture (TECH FIG 5C).
- The apex of the V is folded distally and sutured in place (TECH FIG 5D).
- The proximal length of the V is closed longitudinally with interrupted no. 0 nonabsorbable sutures.
- If further augmentation is required, autograft or allograft of fascia lata, semitendinosus and gracilis tendons, or Mersilene tape can be used.

![TECH FIG 4](image1)

**TECH FIG 4** • A. Proximal tendon edge following débridement of scar tissue. B. Apposition and repair of quadriceps tendon to distal quadriceps stump. C. Incision of inverted V through full thickness of proximal quadriceps tendon. D. Apex of V folded distally and secure in place.

![TECH FIG 5](image2)

**TECH FIG 5** • A. Following débridement of tendon to healthy tissue, excess tension is placed on the tendon for reapproximation. B. Reapproximate the quadriceps edges and secure with sutures. C. Incision of inverted V through full thickness of quadriceps tendon for the purpose of lengthening the tendon as it is reapproximated. D. Apex of V folded distally and secured, as proximal tendon is closed to each other to allow for lengthening and repair of tendon without excess tension.
POSTOPERATIVE CARE

- A long-leg hinged brace with the knee locked in full extension is used for 6 weeks (a long-leg cast may be used for unreliable patients).
- The patient is instructed to observe toe-touch weight bearing for the first 1 to 2 weeks, followed by weight bearing as tolerated with crutches during the remainder of the 6-week period.
- Compliant patients can begin range-of-motion (ROM) exercises within the parameters of the hinged brace, which usually is set from 0 to 90 degrees.
  - This flexion amount is the value attained inter-operatively following complete repair to determine when tension begins stressing the repair.
- At 6 weeks, the long-leg hinged brace is unlocked gradually to full flexion.
- Once 90 degrees of knee flexion is achieved and quadriceps strength is sufficient, use of the brace can be discontinued.
- The patient may advance bearing weight without crutches as function returns.
- Therapy is continued to achieve full ROM and quadriceps strength.

OUTCOMES

- Following acute quadriceps tendon repair and rehabilitation, most patients achieve normal gait, regain full quadriceps strength, and regain satisfactory flexion (some knee flexion may be lost owing to tendon shortening during débridement of necrotic tissue for repair).2,9
- Chronic repairs are associated with persistent quadriceps weakness and extensor lag.
- Older patients often have pre-existing patellofemoral chondromalacia and degeneration, often causing exacerbation of anterior knee pain.5
- Recurrence of tendon rupture is rare.

PEAKS AND PITFALLS

| Proper diagnosis | Complete history and physical examination
| Medial or lateral patellar tilt | Anatomic and balanced repair of medial and lateral retinacula
| Excessive patellofemoral contact stress | Avoid excessive shortening of the extensor mechanism
| Patella baja | Avoid overtightening of the tendon repair.
| Superior patellar tilt | Avoid anterior reattachment of tendon to the superior pole of the patella

COMPICATIONS

- Loss of full knee flexion
- Residual weakness of quadriceps
- Infection
- Wound complications
- Patella tilt
- Excessive patellofemoral contact stress
- Patella baja
- Residual extensor lag

REFERENCES

**DEFINITION**
- **Loss of motion** is a generic term that can refer to a loss of flexion, extension, or both. It does not specifically imply a particular etiology.
- **Flexion contracture** implies a loss of extension secondary to contracture or relative shortening of the posterior soft tissues (capsular or muscular).
- **Arthrofibrosis** describes knee loss of motion (ie, flexion, extension, or both) caused by diffuse adhesions or fibrosis within a joint.
- **Ankylosis** describes immobility of a joint, usually secondary to fibrous, cartilaginous, or bony overgrowth.
- Knee loss of motion is a common and serious complication of knee ligament injury or reconstruction. Surgeon understanding of the pathogenesis, preventive measures, and surgical management of this condition is vital for optimum patient care.

**ANATOMY**
- The knee has been described as a ginglymus (simple hinge-type) articulation.
- In actuality, knee motion is complex and requires at least six degrees of freedom (ie, translation in the anteroposterior, mediolateral, and tibial axial planes with rotational moments corresponding to abduction-adduction, flexion-extension, and internal-external rotation).
- The knee joint consists of three independent articulations: the patellofemoral, medial tibiofemoral, and lateral tibiofemoral articulations.
- Constraint of the knee joint is complex and dynamic. It depends on the position of the knee, the direction and nature of a given load, and the integrity of its bony and soft tissue restraints.
- The knee joint is the largest in the body. Its capsular attachments extend from the suprapatellar pouch proximally to posteromedially and from the posterolateral recesses distally.
- Fibrosis can occur anywhere within these confines and ultimately may lead to loss of motion.
- Normal knee motion varies from person to person.
- Most people achieve some degree of recurvatum in full extension, with men averaging 3 degrees and women averaging 6 degrees of hyperextension.
- Normal knee flexion ranges from 140 degrees in men to 143 degrees in women.
- Slight losses of flexion are much better tolerated than slight losses of extension. Full extension is required to allow quadriceps relaxation during the stance phase of gait. Small deficits in terminal flexion may go unnoticed by all but the elite athlete.

**PATHOGENESIS**
- Loss of motion after a knee injury can vary, depending on patient predisposition, the extent and nature of the injury, the timing and technique of surgery, and postoperative management (Table 1).
- Motion loss in an injured or reconstructed knee can be associated with any of a wide variety of conditions.
- A complete understanding of the terminology associated with knee loss of motion is essential to diagnose and communicate the patient’s condition appropriately (Table 2).
- Each area has its own pathoanatomy and relevant physical findings.

**NATURAL HISTORY**
- Loss of knee motion, particularly extension, can have a tremendous effect on clinical outcomes and overall patient satisfaction.
- Pressures across the patellofemoral joint during stance increase from 0 to 30% of body weight when comparing full extension to a 15-degree flexed position.
- These altered mechanics can lead to pain, apprehension regarding motion, and, ultimately, worsening stiffness. Aggressive intercession via a carefully directed physical therapy protocol or appropriate surgical intervention is essential.

**PHYSICAL FINDINGS**
- Knee motion after ligament reconstruction must be monitored vigilantly.
- Motion should be compared with the contralateral extremity.
- Any loss of motion in the flexion or extension plane should be considered abnormal.

**Table 1**

A complete examination of the knee is essential and can help determine the etiology.

- Inspection
- Swelling or erythema may indicate infection, reflex sympathetic dystrophy, or reinjury.
- Palpation
- Effusion may indicate infection or reinjury.
- Allodynia may indicate reflex sympathetic dystrophy.
- Crepitus may indicate fibrosis, soft tissue calcification, or an anterior cruciate ligament (ACL) nodule.
- A “clunk” may indicate an ACL nodule.
- Range of motion (ROM)
- Extension loss may indicate posterior capsular contracture, infrapatellar contracture syndrome, medial collateral ligament (MCL) calcification, hamstring contracture, notch impingement, ACL nodule, or graft malposition or tension.
- Loss of flexion may indicate quadriceps contracture, infrapatellar contracture syndrome, graft malposition or tension, patellar entrapment, or suprapatellar adhesions.
- Loss of flexion and extension may indicate arthrofibrosis, infection, soft tissue calcification, infrapatellar contracture syndrome, or graft malposition or tension.

**IMAGING AND DIAGNOSTIC STUDIES**

- Plain radiographs—including anteroposterior, lateral, sunrise, and tunnel views—are the essential first step in imaging.
- Hardware failure, osteochondral defects, MCL calcifications, patellar height, patellofemoral alignment, and tunnel placement can be assessed with these images.
- MRI can be obtained to more clearly evaluate the soft tissues.
- The extent and nature of adhesions, graft position, graft failure, and the presence of an ACL nodule can be clarified by MRI.

**DIFFERENTIAL DIAGNOSIS**

- Arthrofibrosis
- ACL nodule
- Graft malposition
- Infection
- Infrapatellar contracture syndrome
- Muscle contracture
- Reflex sympathetic dystrophy

**NONOPERATIVE MANAGEMENT**

- Rest, ice and anti-inflammatory medications should be the first-line intervention for any knee with an acute process as found on physical examination: ie, an inflamed, warm, swollen knee with motion loss.
- Controlled, guided physical therapy is an excellent tool to help regain motion.
- Quadriceps strengthening, active ROM exercises, use of continuous passive motion machines, hanging weights, and extension bracing or casting may all have a role. Each intervention depends on the clinical picture and pathogenesis.
- Our rehabilitation protocol for a multiple ligament knee reconstruction typically involves four phases (Table 3).
- Manipulation under anesthesia has been used by some to improve postoperative motion.4
  - Manipulation should be done with caution, because the procedure itself can cause an inflammatory reaction and lead to further fibrosis.

**SURGICAL MANAGEMENT**

- Failure to progress with nonoperative treatment is a general indication for operative management.
- Identification of the primary cause of the knee stiffness is essential to maximize outcomes.
- Indications for surgical intervention include:
  - Loss of flexion of 10 degrees or more
  - Extension deficits of 10 degrees or more
  - Failure to improve despite 2 months of intense therapy
- The primary goal of operative treatment is restoration of normal knee motion without causing iatrogenic damage to the joint.
- In both acute and chronic knee stiffness, resolution of the inflammatory phase of the condition is mandatory before proceeding with surgical intervention.
- Epidural or regional anesthesia can be used to assist with postoperative pain control to allow more intensive physical therapy in the immediate postoperative period.
- Millett et al10,13 have outlined a systematic nine-step evaluation of potential causes for knee loss of motion, all of which must be addressed whether surgical intervention is performed in an open fashion or arthroscopically.

**Open Surgical Treatment**

- In severe cases of loss of motion of the knee, open releases may be indicated.
- Indications for open débridement and soft tissue release typically include patients with severe arthrofibrosis or patients who have failed previously attempted arthroscopic releases.
- Our general approach is to restore flexion by releasing capsular contractures, by lysing intra-articular fibrosis, and by mobilizing the extensor mechanism.

### Table 2 Terms Associated with Knee Loss of Motion

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arthrofibrosis</td>
<td>Diffuse fibrosis or adhesions</td>
</tr>
<tr>
<td>ACL nodule</td>
<td>Described as a “cyclops lesion,” this is a dense fibrous scar that can form after bone–patellar tendon–bone autograft for ACL reconstruction. It typically is located anterior-lateral to the tibial tunnel and can lead to impingement on the intercondylar notch, preventing full extension.</td>
</tr>
<tr>
<td>Infrapatellar contracture syndrome</td>
<td>Pathologic fibrous hyperplasia of the anterior fat pad leads to adherence of the patellar tendon to the tibia. This leads, in turn, to limited patellar excursion and can be a cause of patella infera.</td>
</tr>
<tr>
<td>Soft tissue calcifications</td>
<td>Calcification and contracture of the capsuloligamentous structures about the knee are a less common, but well-described, cause of motion limitation.</td>
</tr>
<tr>
<td>Muscle contracture</td>
<td>Prolonged immobilization, in either flexion or extension, may lead to deficits in motion due to muscle contracture.</td>
</tr>
</tbody>
</table>
### Chapter 50  KNEE LOSS OF MOTION

#### Table 3  Rehabilitation of Knee Loss of Motion

<table>
<thead>
<tr>
<th>Goals</th>
<th>Program</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Phase I: 0 to 6 weeks</strong></td>
<td>Full-leg hinged knee brace locked in extension for 3 weeks; may begin passive ROM exercises in neutral weeks 4 through 6 and beyond</td>
</tr>
<tr>
<td>Maximum protection of grafts during early healing phase</td>
<td>Patellar mobilization exercises</td>
</tr>
<tr>
<td>Maintain patellar mobility</td>
<td>Straight leg raises in brace</td>
</tr>
<tr>
<td>Maintain quadriceps tone</td>
<td>Cryotherapy</td>
</tr>
<tr>
<td>Control pain and swelling</td>
<td>Non-weight bearing with crutches</td>
</tr>
<tr>
<td>Maintain full passive extension</td>
<td></td>
</tr>
<tr>
<td><strong>Phase II: 6 to 12 weeks</strong></td>
<td>Begin full flexion in brace</td>
</tr>
<tr>
<td>Increase flexion ROM</td>
<td>Partial weight bearing, slowly progress to full weight bearing by postoperative week 10</td>
</tr>
<tr>
<td>Initiate weight bearing</td>
<td>Stationary bike, patella mobilization, prone hangs</td>
</tr>
<tr>
<td>Quadriceps strengthening</td>
<td>Closed chain strengthening after full weight bearing</td>
</tr>
<tr>
<td>Proprioceptive training</td>
<td></td>
</tr>
<tr>
<td><strong>Phase III: 3 to 6 months</strong></td>
<td>Aggressive ROM exercises</td>
</tr>
<tr>
<td>Increase knee flexion to within 10 degrees of uninvolved side by end of 6th month</td>
<td>Advance proprioceptive training</td>
</tr>
<tr>
<td>Improve strength and proprioception</td>
<td>Agility drills/sport-specific practice sessions without contact at 6th month</td>
</tr>
<tr>
<td>Incorporate functional drills</td>
<td></td>
</tr>
<tr>
<td><strong>Phase IV: 6 to 12 months</strong></td>
<td></td>
</tr>
<tr>
<td>Return to sport if minimal pain and swelling, functional strength within 10% of uninvolved side, successful participation in practice drills</td>
<td></td>
</tr>
<tr>
<td>Multidirectional functional brace recommended for sports up to 18 months</td>
<td></td>
</tr>
</tbody>
</table>

- Extension is restored by addressing notch pathology, posterior capsular contractures, and anterior fibrosis.
- **Positioning**
  - The patient is placed supine on the operating table.
  - A pneumatic tourniquet is placed high on the thigh over a cotton wrap. It is not routinely inflated.
- **Preoperative Planning**
  - Examination under anesthesia is performed.
  - Flexion, extension, and patellar mobility should all be assessed preoperatively.
- With the patient fully anesthetized, the hip should be flexed to 90 degrees.
- Gravity should then be allowed to flex the knee. This reveals the true flexion limit.
- With the hip extended, the heel should be supported; the extension limit is then measured.
- Patellar mobility should then be documented with regard to superior–inferior glide, mediolateral glide, and patellar tilt.
- Comparison to the normal, uninvolved knee is extremely useful.

#### ARTHROSCOPIC EVALUATION

- The affected limb is then prepped and draped in standard fashion.
- A side post is utilized under the drapes along the lateral thigh.
- All surgical landmarks and proposed incisions are then drawn on the skin with a surgical marker.
- A surgical timeout is then performed, confirming the patient, the procedure, and the operative limb.
- Perioperative antibiotics are administered within 30 minutes of the surgical incision.
- In severely fibrotic knees, capsular distention using 120 to 180 mL of saline may be necessary to gain safe access to the knee joint without causing iatrogenic damage to the articular cartilage.
- A standard superolateral inflow portal is then created, followed by an inferolateral viewing portal, and, lastly, by an inferomedial working portal.
- Portals are interchanged as necessary, and additional arthroscopic surgical portals are established when necessary (TECH FIG 1).

#### Suprapatellar Pouch

- In a normal knee, a view of the suprapatellar pouch should reveal the vastus intermedius rising off of the femoral shaft.
- The suprapatellar pouch should extend 3 to 4 cm proximal to the superior pole of the patella.
Scarring in the suprapatellar pouch is the most common cause of loss of flexion and, in certain cases, may preclude safe passage of instruments between the femur and patella (TECH FIG 2).

- Lateral or medial retinacular release, or both, may be necessary before suprapatellar pouch débridement can be done.
- Dense fibrous tissue may make it difficult to visualize normal articular cartilage.
- Using a combination of electrocautery, motorized shavers, arthroscopic knives, or heavy scissors, the suprapatellar pouch is reconstituted by performing aggressive releases.
- Care must be employed to avoid damage to the overlying quadriceps tendon or surrounding articular cartilage.

**Medial and Lateral Gutters**

- Adhesions in the gutters also are common causes of flexion loss.
- Dense bands of fibrous tissue course between the femoral condyles and the medial and lateral retinaculi.
- The surgeon should then clear all abnormal tissue, moving proximally to distally from the femur to the retinaculum.
- The gutters should be débrided to the level of the tibial plateau, both medially and laterally.
- Ninety degrees of knee flexion should be attainable at this point of the procedure.
- Failure to reach 90 degrees of knee flexion at this point mandates further débridement of the suprapatellar pouch or medial–lateral gutters.

**Anterior Interval**

- Débridement of the infrapatellar fat pad and pretibial recess is then performed (TECH FIG 3).
- Care must be undertaken to avoid the intermeniscal ligament.
- The release should proceed 1 cm distal to the level of the meniscus along the anterior tibial cortex.
- Hemostasis is essential in the pretibial recess to avoid recurrent scarring of the infrapatellar fat pad.
- Visualization in the anterior interval often can be difficult. A small, medial parapatellar tendon arthrotomy often is used to initiate débridement in the anteroinferior aspect of the knee.

**Lateral and Medial Retinaculum**

- Using electrocautery, selective lateral and medial retinacular releases are performed.
- This improves patellar mobility and increases the effective joint space in the knee.
- Adequate release is achieved when the patella can be everted at least 45 degrees.

**Intercondylar Notch**

- Scarring over the anterior aspect of the ACL, “cyclops” lesions, or graft impingement within the notch can all be addressed.
- A notchplasty is performed if there is evidence of graft impingement as the knee nears maximal extension.
- Cyclops lesions should be débrided and excised.
- In severe cases, malpositioned cruciate grafts may require débridement or release to achieve full extension.
Menisci
- Normal menisci have significant anteroposterior excursion with knee motion.
- In cases of knee stiffness, the menisci can become scarred in a posterior position during knee flexion, which will limit full extension.
- A probe can be used to assess for meniscal mobility.
- If anterior meniscal excursion is poor, a gutter should be created along the periphery of the meniscus from the midbody, working anteriorly until normal mobility is restored.
- This should help achieve full extension, but a posterior capsular release may be necessary in severe cases.

Posterior Capsule
- If full extension cannot be achieved after release of all the tissues just discussed, open posterior capsular release may be indicated.
- Posteromedial and posterolateral approaches commonly are used.
- The posteromedial approach uses an interval between the superficial MCL anteriorly and the pes anserine tendons posteriorly, revealing the underlying medial head of the gastrocnemius and the posterior oblique ligament.
- The posterior oblique ligament is then released from its femoral attachment, and extension is reassessed.
- If extension is still limited, a posterolateral release is necessary.
- The lateral approach courses over the anterior aspect of the biceps tendon distally to the fibular head.
- The short head of the biceps is reflected posteriorly, revealing the lateral head of the gastrocnemius, which often is intimately attached to the lateral capsule.
- The capsule is then incised anterior to the gastrocnemius tendon, releasing the posterolateral capsule.
- Care is taken to avoid the lateral collateral ligament, the popliteus tendon, and the popliteofibular ligament.

OPEN SURGICAL TREATMENT

Open Anterior Release
- Positioning and examination under anesthesia are performed just as described in the arthroscopic section.
- An anterior extensile approach to the knee is used. Previous vertical incisions can be used, or arthroscopic portal incisions may be extended (TECH FIG 4A).
- The subcutaneous tissues are dissected sharply, and full-thickness flaps are raised medially over the extensor mechanism.
- A medial parapatellar arthrotomy is then employed to gain access to the joint.
  - Care must be taken to protect the medial meniscus and the intermeniscal ligament (TECH FIG 4B).
- A medial release is performed by subperiosteally dissecting the soft tissues off of the medial proximal tibia.
- The release is extended posteriorly, and the deep MCL and semimembranosus are elevated to assist in mobilizing the tibia. The insertion of the superficial MCL must be protected.
- Débridement of the medial and lateral gutters is then performed using a combination of finger dissection along with sharp excision of dense adhesions and fibrosis (TECH FIG 4C,D).

TECH FIG 4 • A. Anterior extensile exposure of the knee is used in the open surgical treatment of arthrofibrosis. B. Medial parapatellar arthrotomy is used to gain access to the knee joint. Note the severity of the intra-articular fibrous adhesions. C. Débridement of the medial and lateral gutters using a combination of sharp and blunt dissection. D. A large quantity of pathologic fibrous tissue was excised during the débridement.
POSTOPERATIVE CARE

- If epidural anesthesia or regional blocks were used during the operative procedure, patients may benefit by continuing their use in the postoperative period. Additionally, intra-articular injections of bupivacaine combined with morphine given in the operating room can assist with postoperative pain control.
- Adequate pain relief is essential for the patient to tolerate the immediate postoperative rehabilitation.
- Continuous passive motion (CPM) is used in the immediate postoperative period to assist with knee ROM.
- When patients are not using the CPM machine, they are placed in a hinged knee brace locked in extension.
- Home CPM usually is needed for 2 to 3 weeks.
- Outpatient physical therapy also is implemented early in the postoperative period.
- Gentle ROM exercises are encouraged initially, so as not to exacerbate the inflammatory process that originally created

Extensor Mechanism Release

- The patellar tendon is dissected free from encasing fibrosis on all sides.
- The infrapatellar fat pad is excised in its entirety. The insertion of the patellar tendon on the tibial tubercle must be protected (TECH FIG 5).
- Adhesions between the quadriceps tendon and the distal femur must be released prior to patellar mobilization.
- An inside-out lateral release is then employed, and the patella is then everted or translated laterally to assist with notch visualization.
- Patellar tracking is then assessed throughout the entire ROM.

Notch Débridement

- If full extension is still unattainable at this point of the procedure, graft impingement and malposition must be addressed.
- Residual cyclops lesions are débrided.
- It may be necessary to excise anteriorly positioned ACL grafts, with removal of involved hardware (TECH FIG 6A).
- Posterior capsular contractures can be released by peeling the capsule off the posterior aspect of the femoral condyles.
- The PCL is then evaluated for impingement and is released if found to be a block to extension.
- Finally, a posterior capsular release from the proximal tibia may be needed if full extension has not yet been achieved (TECH FIG 6B,C).

Closure

- Meticulous hemostasis is achieved using electrocautery following deflation of the tourniquet.
- A medium Hemovac drain is placed intra-articularly to reduce postoperative hematoma formation and is left in place for 1 to 2 days.
- The medial parapatellar arthrotomy is closed with absorbable suture if it can be performed without significant tension on the extensor mechanism.
- The subcutaneous tissues and skin are then closed in standard fashion, and compressive dressings are applied.
- The knee is placed in a hinged knee brace and locked if necessary.
the knee loss of motion. Additionally, articular cartilage may be prone to injury by forced motion or excessive activity.

- Prone hangs, knee sags, patellar mobilization, and active quadriceps contraction are emphasized to maintain full extension.
- More aggressive strengthening exercises are begun as the patient continues to progress and improve.
- Multiple modalities are implemented to minimize postoperative swelling and pain.
  - A cryotherapy device is applied in the recovery room and used in both the inpatient and outpatient settings.
  - Nonsteroidal anti-inflammatory medications (NSAIDs) or short courses of oral corticosteroids can be given to reduce inflammation.
  - Compressive dressings are used.
  - Knee aspiration may be necessary for effusions that are large enough to cause pain, inhibit quadriceps activity, or limit ROM.
  - In severe cases, it may be necessary to restrict weight-bearing postoperatively to protect compromised articular cartilage.
  - Initiation of weight-bearing activities is at the surgeon’s discretion.
  - Extension bracing often can be discontinued once patients have full return of quadriceps function.

OUTCOMES

Nonsurgical Results

- Few studies have been written regarding nonoperative management of knee loss of motion.
- Noyes and associates\(^{11}\) reported on 18 patients who did not regain full motion following ACL reconstruction despite implementation of an early active and passive motion protocol.
- Six knees were treated with serial extension casts, nine had early gentle manipulation under anesthesia, and three required arthroscopic lysis of adhesions.
- Thirteen of the 15 patients treated nonsurgically regained full ROM of the knee.
  - In a separate study, Noyes et al\(^{15}\) prospectively evaluated 443 knees and reported that 23 developed arthrofibrosis following ACL reconstruction.
    - Twenty knees (87%) were treated successfully using manipulation under anesthesia, extension casting, and continuous epidural anesthesia.
    - The authors stated that nonsurgical management often can be successful if initiated early.
    - Loss of knee motion that is present more than 3 months following ligament reconstruction surgery is less likely to respond to nonsurgical means.
  - Dodds et al\(^{9}\) evaluated the results of knee manipulations performed for loss of motion in 42 knees that previously had undergone intra-articular ACL reconstruction.
    - The average time from reconstruction to manipulation was 7 months.
    - Ten knees had concomitant arthroscopic débridement.
    - Average flexion increased from 95 to 136 degrees, and extension improved from 11 to 3 degrees.
    - No complications were reported.

Arthroscopic Results

- Most studies in the literature pertaining to knee loss of motion contain a mixed group of patients with varying degrees of severity, chronicity, and etiology. Results should be interpreted based on the specific variant of motion loss.
  - ACL nodule
    - The term “cyclops syndrome” was coined by Jackson and Schaefer\(^{9}\) after reviewing 13 patients with loss of knee extension after ACL reconstruction.
      - All patients were treated with arthroscopic débridement and manipulation. Patients gained an additional 10 degrees of extension and 27 degrees of flexion immediately postoperatively.
      - Motion continued to improve with longer follow-up.
      - Six of the patients required more than one procedure to achieve these results.
      - Marzo et al\(^{11}\) reported on 21 patients with restricted knee extension following ACL reconstruction.
      - All patients had a cyclops lesion at surgery and were treated with arthroscopic débridement, with 10 patients requiring an additional notchplasty for graft impingement.
      - All patients had good results, with an average extension gain of 8 degrees leaving them with an average final extension deficit of 3 degrees.
      - Fisher and Shelbourne\(^{6}\) reported on 42 patients who required arthroscopic débridement for symptomatic extension loss following ACL reconstruction.
      - Both pain relief and ROM improved postoperatively.
      - No complications were reported.
  - Diffuse arthrofibrosis
    - Multiple studies have documented successful treatment of diffuse intra-articular arthrofibrosis with arthroscopic débridement and release.\(^{1,3,17,24–26}\)
    - Shelbourne and Johnson\(^{22}\) reported on nine consecutive patients with symptomatic knee loss of motion following ACL surgery.
      - Eight of the nine patients underwent ACL reconstruction within 2 weeks of the initial injury and were immobilized in flexion postoperatively.
      - The patients underwent arthroscopic débridement of adhesions in the superior patellar pouch, medial and lateral gutters, and in the anterior interval. Notchplasties also were performed followed by manipulations to regain flexion. Extension casting and physical therapy were used postoperatively.
      - At an average of 31 months follow-up, patients had gained 23 degrees of extension and 18 degrees of flexion. Eight of the nine patients returned to sports.
    - Hasan and associates\(^{8}\) reviewed 17 knees with symptomatic extension deficits following ACL reconstruction.
      - All knees were treated with arthroscopic débridement of intra-articular adhesions with excision of cyclops lesions and revision notchplasties.
      - Postoperative ROM yielded 7- and 8-degree improvements in extension and flexion, respectively.
    - Harner and colleagues\(^{7}\) reviewed 21 of 27 patients who developed motion deficits following ACL reconstruction.
      - Fourteen of the patients were successfully treated arthroscopically, although three of those required a second procedure.
      - Six of the knees underwent formal open débridement for more severe intra- and extra-articular adhesions.
      - Sixty-seven percent of the patients had a good or excellent result at final follow-up.
Open Results

- Open débridement and lysis of adhesions are indicated in cases of severe knee loss of motion, infrapatellar contracture syndrome, and failed arthroscopic intervention.

**Infrapatellar Contracture Syndrome**

- Paulos et al. described infrapatellar contracture syndrome (IPCS) as an exaggerated pathologic fibrous hyperplasia of the anterior soft tissues of the knee.
- Patients with this condition presented with loss of knee flexion and extension, patellar entrapment, and patella infera. The authors recommended open débridement in cases with extra-articular involvement.
- Aggressive rehabilitation was done postoperatively.
- Patients gained an average of 12 degrees of extension and 35 degrees of flexion at final follow-up.
- Eighty percent of patients had signs and symptoms of patellofemoral arthritis, however, with 16% of patients demonstrating patella baja.
- A long-term follow-up study of IPCS reported on 75 patients who had undergone previous surgical intervention.
- Depending on the severity of patellar involvement, arthroscopic and open releases were performed. In cases of patella infera, DeLee tibial tubercle osteotomies were performed.
- Significant gains in ROM were achieved, but numerous patients required revision lysis of adhesions and manipulations.
- The authors concluded that the longer the knee was without acceptable motion, the more likely the patient was to have a poor final outcome.
- Richmond and Al Assal reported on arthroscopic treatment of IPCS. Their results revealed a total increase in knee ROM of 45 degrees in 12 patients with that condition.

**Severe and revision cases**

- Millett et al. retrospectively reviewed eight patients who had undergone an open débridement and soft tissue release for severe knee loss of motion.
  - All patients had failed previous arthroscopic intervention. The average arc of motion preoperatively was 62.5 degrees.
  - At final follow-up, the average motion had increased to 124 degrees.
  - Patient satisfaction scores were high, but there was a significant incidence of patellofemoral arthritis.
  - The authors concluded that an aggressive open release is a reasonable option for stiff knees that are recalcitrant to less invasive procedures.
- A recent study detailed a mini-invasive extra-articular quadricepsplasty followed by an intra-articular arthroscopic lysis of adhesions for severe cases of knee arthrofibrosis. Twenty-two patients were treated with the aforementioned technique, in which a five-stage quadricepsplasty is performed to regain knee flexion. Knee arthroscopy was then performed to remove any intra-articular adhesions and to address pathology within the notch and the anterior interval.
- At 44 months of follow-up, the average maximum degree of flexion had increased from 27 to 115 degrees.
- Complications were rare: one superficial wound infection and one persistent 15-degree extension lag were reported.

**COMPLICATIONS**

- The primary complication of surgical intervention for knee loss of motion is recurrence of knee stiffness.
- Rates of reoperation following arthroscopic débridement range from 6% to 43%. Failure of surgical treatment is directly proportional to the severity of the preoperative stiffness.
- The more invasive the procedure necessary to regain full knee motion, the higher is the risk of potential complications.
- Other complications related to arthroscopic or open débridement and release include the following:
  - Skin tearing or necrosis
  - Wound dehiscence
  - Postoperative infection
  - Septic arthritis
  - Neurovascular injury
  - Extensor mechanism disruption
  - Hemarthrosis
  - Patellofemoral pain syndrome

**REFERENCES**

DEFINITION
- Patellofemoral pain is a common symptom in active adolescents and adults.
- The diagnosis of patellofemoral pain is nonspecific. It may be caused by trauma, instability, or overuse. It also may be caused by lateral compression of the patella on the femur.
- The patella is guided through its normal course in the trochlea of the femur by the static soft tissue as well as the dynamic muscular stabilizers.11
- The lateral retinaculum and patellofemoral ligament make up the lateral static soft tissue stabilizers and can lead to painful compression between the patella and femur if excessively tight.
- This scenario has been described as excessive lateral pressure syndrome (ELPS),7 patellar compression syndrome,14 and patellofemoral stress syndrome.14
- This chapter describes the surgical treatment of ELPS.

ANATOMY
- The patella acts as a fulcrum and provides a smooth surface on which the extensor mechanism can function.3
- The thickest articular cartilage in the body is located in the patellofemoral joint.
- Forces across the patellofemoral joint are about three times body weight during ascending and descending stairs and can reach up to 20 times body weight during activities such as jumping.3
- As the knee flexes from a fully extended position, the patella is drawn into the trochlear groove at approximately 20 degrees.
- In extension, the medial patellofemoral ligament is the primary restraint to excessive lateral translation.
- In early flexion, the lateral trochlear ridge is the primary restraint.
- A tight lateral retinaculum and patellofemoral ligament are responsible for constricting the patella in ELPS.

PATHOGENESIS
- An abnormally tight lateral retinaculum can cause pressure and subsequent pain and degeneration of articular cartilage on the lateral aspect of the patella as it encounters the femoral condyle.
- Some conditions, such as a weak vastus medialis obliquus, malalignment (abnormal Q angle), internal tibial torsion, and femoral anteversion predispose to lateral tracking.
- Other conditions, such as direct trauma (eg, dashboard injury) and dislocation, can result in degeneration of the lateral patellofemoral articular cartilage.

NATURAL HISTORY
- No good long-term natural history studies of ELPS have been reported to date.
- It is well known, however, that disruption of articular cartilage results in progressive degenerative changes.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically report insidious onset of anterior knee pain that is activity-related, although some may have experienced trauma in the past.
- Pain typically is exacerbated by prolonged sitting and stair climbing.
- Symptoms and clinical findings of instability do not play a part in ELPS.
- A thorough physical examination should include the following:
  - Examination for effusion. Effusion may indicate traumatic or degenerative disruption of the articular surface.
  - Observation of patellar tracking (J-sign)
  - Patellar tilt test. If the lateral facet cannot be tilted to neutral, the lateral retinaculum is abnormally tight.
  - Patellar glide test. A lateral glide of up to two quadrants is normal. More than this may indicate excessive lateral translation. Comparison should be made to the normal extremity.
  - Patellar apprehension test. Apprehension suggests an unstable patella.
  - Examination for quadriceps tightness, which often is associated with patellofemoral pain.
  - Patellar grind test. Pain may indicate patellofemoral arthritis but also may be found in normal articular surfaces.
  - Inspection for bony knee malalignment (Q angle)

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs of the knee should include anteroposterior, tunnel, Merchant (sunrise), and 30-degree lateral views. If arthritis is suspected, a posteroanterior flexed 45-degree view should be obtained.
- Lateral subluxation can be measured on the Merchant radiograph. If the line through the patellar apex is lateral to a line bisecting the trochlear sulcus angle, then the patella is subluxed laterally (FIG 1A).
- A CT scan is the best way to evaluate patellar tilt radiographically. Using an axial image, a line is drawn parallel to the posterior femoral condyles and is compared to a line along the lateral patellar facet. If these lines converge laterally, then the patella has excessive lateral tilt (FIG 1B).
- An MRI may be beneficial in evaluating the integrity of articular cartilage and also may show concomitant meniscal and ligamentous pathology (FIG 1C).

DIFFERENTIAL DIAGNOSIS
- Patellofemoral pain (without excessive lateral pressure syndrome)
- Patellar instability
- Lateral meniscal tear
- Patellar fracture
■ Iliotibial band syndrome
■ Prepatellar bursitis
■ Neuroma
■ Osteochondritis dissecans of the patella or trochlea

NONOPERATIVE MANAGEMENT
■ The mainstay of treatment is nonoperative, with most patients benefiting from quadriceps stretching and selective strengthening exercises.
■ Oral analgesics and bracing also can be beneficial.
■ Corticosteroid injection or viscosupplementation may be helpful in patients with concomitant arthritis.

SURGICAL MANAGEMENT
■ The indication for lateral retinacular release is failure of an adequate trial of rehabilitation in a patient with symptomatic patellofemoral pain, excessive lateral retinacular tightness, and lateral tilt.8
■ Lateral release usually is not a successful treatment for lateral patellar instability and, in some cases, can result in iatrogenic medial patellar instability.
■ Successful lateral retinacular release can be performed using either arthroscopic or open techniques.

Preoperative Planning
■ Range of motion, patellar tilt and subluxation, and ligamentous stability should be examined while the patient is under anesthesia.
■ Particular attention should be paid to patellar tracking as the knee is taken through a range of motion (ROM).
■ The operative knee should be compared to the contralateral side.

Positioning
■ The patient is placed in the supine position with the operative leg supported according to the surgeon’s preference for standard knee arthroscopy (FIG 2).
■ A nonsterile tourniquet is placed around the thigh.

Approach
■ A superolateral inflow portal is established just lateral to the vastus lateralis obliquus.
■ Standard inferomedial and inferolateral portals are used.

FIG 2 • Patient positioning for standard knee arthroscopy using a leg holder and superolateral portal.
ARTHROSCOPIC LATERAL RELEASE

- Diagnostic arthroscopy is performed with the 30-degree arthroscope placed in the anterolateral portal.
- The entire knee is examined to rule out concomitant intra-articular pathology.
- The posteromedial and posterolateral compartments are visualized using the Gillquist technique.
- Meniscal tears, articular cartilage lesions, and loose bodies are identified and addressed surgically when indicated.
- Patellofemoral tracking is visualized as the knee is put through its ROM.
- Once the diagnostic arthroscopy is completed, an Esmarch bandage is used to exsanguinate the leg, and the tourniquet is inflated.
- The camera is placed in the inferomedial portal and a hooked coagulation device in the inferolateral portal.
- Under direct arthroscopic visualization, the release is started just distal to the inflow cannula (TECH FIG 1A).
- First the synovium is cut, exposing the underlying retinaculum.

The retinaculum, which has a distinct firm feel, is then cut using multiple passes with the electrocaudery device (TECH FIG 1B).
- The release should extend down to the level of the inferolateral portal.
- Great care should be taken to not cut the vastus lateralis muscle or tendon.
- If the superior lateral geniculate vessels are seen, they should be aggressively coagulated.
- Patellar tilt is assessed after release. The surgeon should be able to tilt the patella 30 to 45 degrees with the knee fully extended.
- Excessive lateral release may result in medial instability.
- After the release is completed, the tourniquet is gradually deflated to assess for excessive bleeding.
- The portal sites are closed, and a sterile compression dressing and cryotherapy device are applied.
- Use of a drain may be considered on a case-by-case basis.

PEARLS AND PITFALLS

| Indications | The indication for isolated lateral release is retropatellar pain from the lateral patellofemoral joint secondary to soft tissue tightness. Lateral retinacular release should not be performed as an isolated procedure if patellar instability is the primary problem.⁸,¹⁷ |
| Instability | It is important to not transect the vastus lateralis obliquus muscle and tendon during release, because that can predispose to medial instability. |
| Hemostasis | The superior lateral geniculate vessels are at risk during lateral release. Deflating the tourniquet before closing can help identify excessive bleeding. Use of a cryotherapy device and a compression dressing will also decrease the risk of hemarthrosis. |
| Landmarks guiding length of release | The superolateral inflow cannula is an excellent guide for the most proximal starting point of the release. The release should extend distally to the inferolateral portal. |

POSTOPERATIVE CARE

- A compression dressing and a cryotherapy device are used to decrease risk of hemarthrosis.
- Patients are allowed to progress to weight bearing as tolerated and discard crutches when they are ambulating safely.
- Patients are initially seen 1 week after surgery to assess knee motion and quadriceps function and to remove sutures.
- Some patients benefit from formal physical therapy for ROM and quadriceps strengthening to facilitate return to normal function.

OUTCOMES

- Arthroscopic isolated lateral retinacular release has a success rate ranging from 70% to 93%.¹²,¹³,¹⁵
One prospective, randomized study found that 93% of patients returned to presymptomatic activity level.

The same study found quadriceps strength deficits in 40% of patients, but in almost all cases the strength was within 10% of the normal leg.

Arthroscopic and open techniques have similar success rates. Arthroscopic and open techniques have similar success rates.

Success rates of lateral release are lower when performed for instability alone or when advanced patellofemoral arthritis is present.

COMPLICATIONS

Hemarthrosis is the most common complication, followed by infection. Medial instability from overaggressive release can be especially difficult to manage. The diagnosis of medial instability can be difficult to make. Patients may report a sensation of lateral instability if the patella sits in a medially subluxed position during early flexion, then snaps laterally during continued flexion. This is important because if the clinician incorrectly treats the presumed lateral instability with a medial stabilization procedure, the symptoms could worsen.

Other potential complications include quadriceps tendon rupture, patella baja, thermal injury, and arthrofibrosis.

REFERENCES

DEFINITION

- In most cases, patellar dislocation results in injury to the medial retinacular ligaments, including the medial patellofemoral ligament (MPFL), leading to increased lateral patellar mobility.
- The MPFL is the primary ligamentous restraint against lateral patellar displacement.
- Competency of the MPFL is both necessary and sufficient to restore lateral patellar mobility to a normal range; consequently, surgical treatment should aim for restoration of a functional MPFL.

ANATOMY

- The main stabilizer of the patella in normal knees is the bony congruence between the patella and trochlear groove.
  - When the trochlear groove is dysplastic, as it is in many patients with patellar instability, the medial retinacular ligaments (ie, the MPFL) take on a greater role.
  - Even in the presence of a normal trochlea, MPFL deficiency can result in symptomatic lateral patellofemoral instability.
- The patellotibial and patellomeniscal ligament complex play a secondary role in restraining lateral patellar displacement, whereas the medial patellofemoral retinaculum contributes little to patellofemoral stability.
- The MPFL is an extra-articular ligament that lies in layer 2, between the medial retinaculum superficially and the joint capsule on its deep surface. The vastus medialis obliquus (VMO) tendon lies superficially anteriorly and inserts onto the anterior third of the MPFL.
- In a recent cadaveric study, the MPFL was moderately or well developed in 17 of 20 (85%) specimens, and poorly developed in 3 of 20 (15%).
- The MPFL is about 58 mm long, with a width and thickness of 12 mm and 0.44 mm, respectively, at its midpoint.
- The MPFL fans out anteriorly, inserting on the proximal two thirds of the patella.
- The femoral attachment of the MPFL is posterosuperior to the medial femoral epicondylye and just distal to the adductor tubercle when the knee is fully extended. The center of the anterior edge of the femoral attachment is located 9.5 mm proximal and 5.0 mm posterior to the center of the medial femoral epicondylye (FIG 1).

PATHOGENESIS

- Patellar dislocations usually occur when the foot is planted, the knee is partially flexed, and the body pivots abruptly, resulting in internal rotation of the femur. Patients may or may not have sustained a direct blow.
- Patients may report that something “popped out” medially, as the uncovered medial femoral condyle becomes prominent.
- The knee usually gives way secondary to pain inhibition of the quadriceps and disruption of the mechanical advantage of the extensor mechanism, and the patient falls down.
- If the knee remains flexed, the patella may remain dislocated over the lateral femoral condyle.
- The history of injury may be unclear, especially if the patella rapidly and spontaneously reduced.
- In one cohort of 189 patients, 61% of first-time dislocations occurred during sports activity.

NATURAL HISTORY

- Fithian et al reported a 17% incidence of redislocation in a cohort of first-time dislocators followed over 2 to 5 years.
- On the other hand, patients presenting with recurrent patellar instability are much more likely to continue experiencing additional dislocations than patients who present with their first dislocation.
  - The risk of a repeat dislocation in patients presenting with a history of prior patellar dislocation is about 50% over a 2- to 5-year period.
  - The strongest risk factor for recurrent patellar instability is a history of prior patellar subluxation or dislocation.
  - Other risk factors include female gender and younger age (less than 18 years old).
  - In one study, girls with open tibial apophyses had the worst prognosis for instability.
- It is unclear whether patellar dislocation leads to premature arthritis.
  - Crosby and Insall reported that degenerative changes were uncommon after patellar dislocation.
  - In a more recent study, however, the incidence of degenerative changes was significantly higher at 6- to 26-year follow-up in first-time dislocators treated nonoperatively.

FIG 1 • Schematic diagram of the medial knee. The medial patellofemoral ligament (MPFL) arises between the adductor tubercle and medial epicondylye, then runs forward just deep to the distal vastus medialis obliquus (VMO) to attach to the superior two thirds of the medial patellar margin.
PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient should be asked about mechanical complaints of locking or catching, because osteochondral loose bodies off the medial patellar facet or lateral trochlea (kissing lesion), impaction fracture of the lateral femoral condyle, or avulsion fragments off the medial patella may result from a patellar dislocation.
- Physical examination should include:
  - Lateral-medial patellar translation. Increased laxity is signified by more than two quadrants of translation; 10 mm or more of lateral translation; or the absence of an endpoint.
  - Apprehension sign. Inability to fully translate the patella laterally because of patient guarding may lead to a false-negative result.
  - J-sign. The patella abruptly translates laterally as the knee is fully extended, moving in an upside-down “J” pattern.
  - Check-rein sign. A positive test (no endpoint) signifies MPFL laxity (analogous to a Lachman test).
  - Patellar facet palpation. Tenderness may indicate an osteochondral or avulsion injury.
  - Medial retinacular palpation. Tenderness may indicate retinacular injury. A palpable defect may be felt in the retinaculum or even the VMO.
  - Effusion. A tense effusion or hemarthrosis (on aspiration) after an acute dislocation raises suspicion for an osteochondral fracture. MRI or arthroscopy should be considered.
- The examination also should evaluate associated injuries and rule out differential diagnoses:
  - Anterior cruciate ligament (ACL) injury results from a similar noncontact pivoting mechanism and also leads to an acute effusion. The Lachman test is highly sensitive for an ACL disruption. Pivot shift also may be attempted, but may be difficult to perform on an acutely injured knee. To rule out ACL injury definitively, ligament arthrometry or stress radiography is recommended for all patients presenting with knee injury.
  - If posterior cruciate ligament (PCL) injury is suspected, the patient is checked for normal tibial stepoff with the knee flexed to 90 degrees. A posterior drawer and quadriceps active test also may be done.
  - Medial collateral ligament (MCL) and lateral collateral ligament (LCL) injuries result in joint space opening with valgus or varus stresses, respectively. These tests are performed in both full extension and 30 degrees of flexion. Comparison stress radiographs can be useful to control for individual variation.
  - A posterolateral corner (PLC) injury results in 10 degrees or more of external rotation asymmetry (dial test) and a positive posterolateral drawer test.
  - Medial patellar instability can occur following prior lateral retinacular release. Medial patellar instability can be distinguished from lateral instability by the DeLee sign. The patient is placed in the lateral decubitus position with the injured side up. With medial patellar instability, gravity subluxates the patella medially. As the knee is flexed, the patella reduces in the trochlea with pain. The DeLee sign is positive if the application of a laterally directed force on the patella (which reduces the patella from its subluxated position) eliminates the pain caused by flexion of the knee.
  - Meniscal tears are indicated by joint line tenderness and also possibly by positive McMurray and Appley’s grind tests.
  - Diagnosis of extensor mechanism disruption should be obvious based on an inability to straight-leg raise and actively extend the knee.
  - Patellofemoral osteoarthritis may be obvious on plain radiographs, but early stages require MR arthrography or arthroscopy for diagnosis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Recommended plain radiographs include a standing anteroposterior view, a true lateral view with the knee flexed 30 degrees, and a standard axial patellar view at 30 or 45 degrees flexion.
- On the lateral radiograph, patellar height is measured according to the method of Caton and Deschamps (ie, the ratio of the floor of the trochlea crosses the anterior border of both femoral condyles (crossing sign)\(^4\) (FIG 2A). Alternatively, the positive trochlear prominence (ie, the sagittal distance between the trochlear groove and the anterior femoral cortex) on the lateral view has been shown to correlate well with trochlear dysplasia\(^4,5\) (FIG 2B). A trochlear groove prominence of 3 mm indicates trochlear dysplasia (FIG 2C).
- The axial patellar view may demonstrate lateral patellar subluxation or even frank dislocation. It may demonstrate medial patellar avulsion fractures, although these may be missed on plain radiographs.
- Stress radiography has been advocated to demonstrate abnormal patellar mobility.
  - With the knee flexed to 30 degrees, an axial patellar view is taken with a laterally directed force applied to the medial side of the patella.
  - Measurements are made on both the symptomatic and asymptomatic knees.
  - A side-to-side increase of 3.7 mm of lateral translation on the symptomatic side compared to the asymptomatic side is considered abnormal.\(^24\)
  - MRI identifies osteochondral injuries on the patella and femur, as well as loose bodies, that may be missed on plain radiographs.
  - A tense effusion should be aspirated.
  - Presence of gross hemorrhrosis on joint aspiration is an indication for MRI to assess for osteochondral fracture and loose body.
  - The TT–TG offset is the transverse distance between the anterior tibial tuberosity (TT) and the center of the trochlear groove (TG).\(^4\)
  - It can be measured on axial CT or MRI (FIG 2D).
  - Lateral offsets of 20 mm or more should be corrected with medialization of the tibial tubercle.
FIG 2 • A. On a true lateral radiograph, trochlear dysplasia is evident when the floor of the trochlea crosses the anterior borders of both femoral condyles (ie, the “crossing” sign). B. Measurement of the trochlear prominence on the lateral view according to Dejour et al. X and Y are lines tangential to the anterior and posterior cortices of the distal femoral metaphysis, respectively. Line Z crosses the most prominent point of the line of the trochlear groove (point B) and the upper aspect of the posterior border of the condyle. Line Z crosses the anterior aspect of the lateral condyle (point A) and line X (point C). The distance BC (in mm) is the trochlear prominence. C. Lateral radiograph demonstrating a knee with positive trochlear prominence. Note that the floor of the trochlea lies anterior to the line tangential to the anterior cortex of the distal femur. D. Measurement of the tibial tuberosity–trochlear groove (TT-TG) offset, the transverse distance between the apex of the anterior tibial tuberosity and the center of the trochlear groove. Measurements are made on superimposed axial CT or MRI images. E,F. MPFL injury appearance on MRI. E. Transverse gradient-echo image of the knee obtained at the level of the insertion of the adductor magnus tendon 3 weeks after lateral patellar dislocation demonstrates a complete tear of the femoral origin of the MPFL, with MPFL fibers retracted anteriorly (solid arrow). Partial injury, with surrounding edema, to the midsubstance of the patellar retinaculum (open arrow) also is seen. F. Transverse gradient-echo image of the knee in a different patient 2 days after lateral patellar dislocation showing partial injury to the femoral origin of the MPFL. The MPFL fibers (solid white arrow) are wavy and show longitudinal split, and there is extensive surrounding edema. A complete tear (open arrow) is seen in the patellar insertion of the medial patellar retinaculum. A large joint effusion with layering (black arrows) is present, consistent with hemarthrosis. Note also the inferior fibers of the VMO (arrowheads).

- MRI also is useful in identifying the location and degree of medial soft tissue injury preoperatively.
- MPFL injuries occur commonly in the form of tears near the femoral attachment or avulsions off the femur, but also may occur as midsubstance tears or avulsions off the patella (FIG 2E,F). Injuries to multiple sites in the medial ligamentous stabilizers may occur.5

DIFFERENTIAL DIAGNOSIS
- Ligament/capsular injury (ACL, PCL, MCL, LCL, PLC)
- Osteochondral injury
- Medial patellar dislocation
- Extensor mechanism disruption
- Meniscal tear
Chapter 52  PROXIMAL REALIGNMENT OF THE MEDIAL PATELLOFEMORAL LIGAMENT

- Patellofemoral osteoarthritis
- Contusion

**NONOPERATIVE MANAGEMENT**
- Nonoperative treatment usually is indicated for acute, first-time dislocators without associated osteochondral fracture and loose bodies.
- Randomized prospective studies comparing operative and nonoperative treatment of initial patellar dislocation found no benefit from immediate medial retinacular repair.
- Although there is evidence suggesting that immobilization following patellar dislocation may lower the risk of redislocation, patients often do not accept prolonged cast or splint immobilization. As a result, nonoperative management relies on brace protection during early progressive mobilization and functional rehabilitation.
- After an acute dislocation, patients initially are placed in knee immobilizers for comfort and weight bearing as tolerated.
- As soon as comfort allows, passive ROM exercises and resisted closed-chain exercises in a patella-stabilizing brace are begun.
- Patients are allowed to return to stressful activities, including sports, on resolution of the effusion, attainment of a full ROM, and return to at least 80% of their quadriceps strength compared to the noninjured limb.
- Patients are encouraged to continue wearing the patella-stabilizing brace during participation in pivoting activities and sports.

**SURGICAL MANAGEMENT**
- An associated osteochondral fracture and loose body occurs in 3% to 4% of first-time dislocators and is an indication for acute surgical treatment.
- In this case, primary MPFL repair should be performed after fixation of the osteochondral fracture. Preoperative MRI can help in localizing the site of MPFL injury.
- Surgical management usually is indicated for any patient with at least two documented patellar dislocations and a physical examination demonstrating excessive lateral patellar laxity.
- For these recurrent dislocators, MPFL reconstruction should be done.

**Preoperative Planning**
- Appropriate imaging studies should be reviewed.
- Plain radiographs should be reviewed for the presence of trochlear dysplasia (ie, a cross sign and trochlear prominence of 3 mm or more), avulsion fractures, and loose bodies.
- If signs of trochlear dysplasia are present, an axial CT or MRI scan should be obtained to measure the TT-TG offset. Offset of 20 mm or more should be treated with medialization of the tibial tubercle.
- If patella alta is present (ie, Caton-Deschamps ratio of 1.2 or greater), then distalization of the tibial tubercle should be considered.
- MRI scans should be reviewed for the presence of avulsion fractures, osteochondral fractures, and loose bodies.
- If MPFL repair is to be performed, MRI should be reviewed to identify all locations of MPFL disruption. Failure to identify and treat each location of MPFL disruption may jeopardize the repair.
- Examination under anesthesia should confirm excessive lateral patellar mobility.
- The patella should displace more than 10 mm laterally from the centered position with the knee flexed 30 degrees, and there should be a soft endpoint or no endpoint with the knee extended.

**Positioning**
- The patient is positioned supine.
- If an osteochondral fracture and loose body amenable to reduction and fixation are present, surgery may proceed with an open approach (see Primary MPFL Repair at the Patellar Insertion, in the Techniques section).
- If a diagnostic arthroscopy is performed before MPFL reconstruction, then the limb is placed in an adjustable leg holder to adjust knee flexion during the procedure.

**Approach**
- The surgical approach depends on whether a primary MPFL repair or reconstruction is to be performed.
- During MPFL repair, the surgical approach is determined by the location of MPFL and retinacular injury. MPFL injury may be seen as a proximal or distal avulsion, or as a tear near the femoral origin, the midsubstance, or the patellar insertion. Multiple sites of injury may coexist.

**DIAGNOSTIC ARTHROSCOPY**
- Standard anterolateral and anteromedial portals are used.
- A superolateral portal is used to facilitate viewing of the patellar articular surface and passive patellar tracking and mobility.
- Articular cartilage lesions are addressed.
- Specifically, the patellofemoral compartment is assessed for the severity of articular cartilage injury and the presence of degenerative changes.
- Unstable cartilage flaps are débrided.
- Loose bodies are removed.

**PRIMARY MPFL REPAIR AT THE PATELLAR INSERTION**
- A midline skin incision is made extending from the superior pole of the patella to the midaspect of the patellar tendon.
- After dissection through the subcutaneous tissue, the superficial medial patellar retinaculum (layer 1) is identified. It is incised and reflected medially, exposing the underlying MPFL.
- The MPFL is inspected both visually and digitally along its entire length to identify all sites of injury.
- The deep synovial layer (layer 3) can be dissected off the deep surface of the ligament to aid in inspection.
- The knee is then flexed to 30 degrees with the patella manually reduced in the trochlear groove.
TECHNIQUES

- Avulsions are repaired with suture anchors.
- Tears of the substance of the MPFL are repaired with no. 2 Fiberwire (Arthrex, Naples, FL) in a modified Kessler fashion (TECH FIG 1).
- After the repair, proper tensioning is assessed.
  - The knee is taken through a full passive ROM to evaluate patellar tracking, looking for abrupt or gradual deflection of the patella that might indicate either excessive or insufficient medial tightening.
- The femoral origin of the MPFL may be accessed through an extensile midline skin incision.
  - Alternatively, the origin may be approached through a separate posterior incision centered between the medial epicondyle and the adductor tubercle.
  - The dissection is carried down through the subcutaneous tissue, and the injured medial retinacular tissue is identified.
  - MPFL avulsions off the femur are repaired with suture anchors placed at a point 9 mm proximal and 5 mm posterior to the medial epicondyle, just distal to the adductor tubercle.
  - To augment the repair, a 10-mm × 60-mm strip of medial retinacular tissue (layer 1) is dissected off the femur, leaving the patellar attachment intact (TECH FIG 2).
  - This medial retinaculum strip may be placed over the repaired MPFL and anchored into the adductor tubercle using a cancellous screw and either a spiked washer or suture anchor.

AUGMENTED MEDIAL PATELLOFEMORAL LIGAMENT REPAIR AT ITS FEMORAL ORIGIN

- With the knee extended, a laterally directed force should reproduce a firm endpoint ("check rein" sign).
- Patellar mobility is assessed by applying medial and lateral forces of about 5 pounds with the knee flexed to 30 degrees. This should produce 5 to 10 mm of medial and lateral translation, respectively. If lateral displacement is less than 5 mm or more than 10 mm, then the medial repair is retensioned.
- The wound is closed in layers.

TECH FIG 1 • A. Disruption of the medial patellofemoral ligament (MPFL) near its femoral origin. B. For repair at this site, the superficial medial patellar retinaculum (layer 1) is reflected medially, exposing the torn MPFL. With the knee flexed 30 degrees, midsubstance MPFL tears are repaired primarily while avulsions are repaired using suture anchors.

MEDIAL PATELLOFEMORAL LIGAMENT RECONSTRUCTION

Semitendinosus Tendon Graft Harvest and Preparation

- The sartorial fascia is exposed through a 2- to 3-cm skin incision made 2 cm medial and distal to the medial border of the tibial tubercle (TECH FIG 3).
- The sartorial fascia is incised in line with the palpable gracilis tendon.
  - Avoid making this incision too deep, to avoid injury to the underlying superficial MCL.
- Identify and isolate both the gracilis (proximal) and semitendinosus (distal) tendons from their deep aspect, ie, from within the bursal layer.
- Apply tension to the semitendinosus while freeing it from the crural fascia at the posteromedial corner with tissue scissors.
- Place stay sutures of no. 0 or 1 absorbable on a tapered needle, and then divide the tendon from the tibial insertion.
- Once all tendinous slips have been freed, harvest the semitendinosus tendon using a closed (preferred) or open tendon stripper.
- Baseball stitches are placed on both free ends for later graft passage through the two patellar tunnels. The remaining free ends are discarded after graft fixation.
- The graft is prepared on the back table by first sizing the graft to 240 mm, then folding it in half, leaving a doubled graft of 120 mm. The excess is removed.
- A pullout suture of no. 5 polyester is placed through the loop to be used for pulling the doubled graft into the blind femoral tunnel.
- A baseball stitch 25 mm in length is placed in the looped end of the graft.

Patellar Tunnel Placement

- A longitudinal incision the length of the patella is made at the junction of the medial and middle thirds of the patella (in line with the medial border of the patellar tendon at the distal patellar pole).
- The medial 8 to 10 mm of the patella is exposed by subperiosteal dissection with a no. 15 scalpel.
- The dissection extends medially and dorsally around the patella through layers 1 (longitudinal retinaculum) and 2 (native MPFL), stopping after the transverse fibers of the native MPFL have been cut. The capsule (layer 3) is left intact (TECH FIG 4A).
- A 4.5-mm drill hole is placed on the medial side of the upper pole of the patella adjacent to the articular margin (TECH FIG 4B).
- A corresponding drill hole is placed on the anterior surface of the patella approximately 8 mm from the
medial border (this point corresponds to the lateral edge of the original retinacular dissection).
- The two drill holes are connected with a curved curette.
- A second 4.5-mm drill hole is placed on the medial side of the patella at a point two thirds down the length of the patella.
- Again, a corresponding drill hole is placed on the anterior surface of the patella about 8 mm from the medial border, and the two holes are connected with a curved curette.
- If the semitendinosus graft is more than 4.5 mm in diameter, the drill holes are enlarged slightly to facilitate graft passage.
- It is important to avoid placing the distal patellar tunnel distal to the native insertion of the MPFL to avoid constraining the distal pole of the patella.

**Femoral Tunnel Placement and Checking Isometry**
- A skin incision is made just anterior to the palpable ridge connecting the medial femoral epicondyle and the adductor tubercle (see Tech Figs 3 and 4).
- The knee is flexed slightly to facilitate palpation of this landmark (flexion moves the hamstrings posteriorly away from the medial epicondyle).
- If the patient is obese and the landmarks are difficult to palpate, a small skin incision is made and palpation is done through the wound to identify the ridge.
- The graft may be placed between layers 1 and 2 or between layers 2 and 3 (joint capsule) (ie, it may lie superficial or deep to the native MPFL).
- Placing the graft between layers 2 and 3 is preferred, because blind dissection superficial to the native MPFL may disrupt the insertion of the VMO into the anterior portion of the MPFL; in addition, by placing the graft deep to the native MPFL, the latter may be repaired to the graft during wound closure.
- The graft should not be placed deep to the capsule, because it should remain extra-articular to avoid graft abrasion and facilitate complete healing.
- Using a long, curved clamp, the selected interval is developed (again, preferably between layers 2 and 3) from the patellar incision anteriorly to the medial femoral epicondyle posteriorly.
- With the tip of the clamp overlying the ridge between the medial epicondyle and adductor tubercle, layers 1 and 2 are incised using a no. 15 blade.

**Graft Passage and Fixation**
- No. 5 suture is passed through the Beath pin on the looped end of the graft, and the pin then is advanced out the lateral femoral cortex to pass the graft into the femoral tunnel.
- Fixation to the femur may be achieved reliably with a 20-mm absorbable interference screw.
- The looped isometry suture, if left in place in the retinacular tunnel, may be used to pass the free ends of the graft through the retinacular interval created previously (TECH FIG 5A, B).
- The free graft arms are passed individually through their respective patellar tunnels using double 22-gauge stainless steel wire or a curved suture passer.
- The graft arms enter the medial border of the patella and exit anteriorly (TECH FIG 5C).
- The free graft arms are then doubled back and sutured on themselves just medial to the patella using two figure 8 mattress sutures of no. 2 nonabsorbable suture on a tapered needle.

**TECH FIG 5 • A.** The synthetic isometry suture is in place. After correct placement of the femoral attachment site is confirmed using the isometry suture, the semitendinosus graft has been fixed to the femur using an interference screw. **B.** The isometry suture is used to shuttle the graft anteriorly out the medial patellar incision. The graft will then be fixed to the two patellar tunnels. (continued)
Graft arms are passed through the 2 patellar tunnels and sutured back onto themselves.

Interference screw in blind femoral tunnel

MPFL graft tunneled between layers 2 and 3 of the medial retinaculum

TECH FIG 5 * (continued) C. Schematic diagram demonstrating fixation of the graft posteriorly into a blind femoral tunnel, and anteriorly to two patellar tunnels. At the patella, each limb of the graft enters into respective medial drill hole, exits the anterior drill hole, then is sutured back to itself medial to the patella.

- Patellar mobility is checked after the first suture is placed. There should be a good endpoint, or checkrein, with the knee in full extension and at 30 degrees of flexion, full knee ROM, and 7 to 9 mm of lateral patellar displacement from the centered position at 30 degrees of flexion.

- Excess graft is sharply removed.

- The native MPFL is sutured to the graft, and then the retinaculum is closed over the graft.

- The wounds are closed in standard fashion.

**PEARLS AND PITFALLS**

**Indications**
- Perform examination under anesthesia to confirm excessive lateral patellar mobility.
- Perform arthroscopy to stage articular cartilage lesions and rule out preexisting arthritis, a contraindication to MPFL reconstruction.

**Femoral tunnel placement**
- This is one of the most critical steps in the operation.
- Adjust the tunnel placement to ensure appropriate graft behavior during flexion and extension, recreating isometry.

**MPFL graft tensioning**
- Center the patella in the patellar groove and ensure that the MPFL graft is lax throughout a range of motion, becoming tight only when the patella is displaced laterally from its centered position.
- The patella should enter the trochlea from the lateral side as the knee is flexed.

**Overtightened graft resulting in excessive medial constraint**
- If the patella enters the trochlea from the medial side as the knee is flexed or if there is less than 5 mm of lateral patellar glide with gentle manual force at 30 degrees of knee flexion, then the graft is overtensioned. The sutures should be removed and the graft retensioned.

**Breakage of patellar bone bridge**
- May occur during preparation of the two patellar tunnels or during passage of an oversized graft through a tight patellar tunnel.
- If this occurs, then drill a second exit hole more laterally on the anterior patellar surface or drill the tunnel transversely across the patella, exiting at the lateral patellar margin.
- The graft can be secured by tying the sutures over a button or suturing the end of the graft to the soft tissues on the lateral patellar border.
POSTOPERATIVE CARE

- Weight bearing as tolerated is allowed immediately postoperatively in a drop-lock or knee extension brace.
- Bracing may be continued for up to 6 weeks during ambulation to prevent falls until quadriceps control is restored.
- After the soft tissue procedure, passive ROM exercises and resisted closed-chain exercises are begun as soon as possible to restore ROM and quadriceps control.
- If a tibial tubercle osteotomy is performed, passive ROM using heel slides is begun postoperatively. No active extension is allowed for 6 postoperative weeks. At that time, full active ROM is begun, followed by closed-chain resistance exercises at 3 postoperative months.
- Patients are allowed to return to stressful activities, including sports, when they attain full ROM and have regained at least 80% of their quadriceps strength compared to the noninjured limb.
- If at least 90 degrees of flexion is not achieved by 6 postoperative weeks, then the intensity of the therapy program must be increased; manipulation under anesthesia (MUA) may be needed between 9 and 12 postoperative weeks if stiffness does not resolve with therapy alone.

OUTCOMES

- In a series of 92 knees treated with MPFL reconstruction, Fithian et al17 reported only 7 failures or reoperations (7.6%) and only one case of frank patellar redislocation (1.1%). Most of the reoperations were for stiffness and were treated successfully with MUA.
- Schottle et al22 reported 86% good and excellent results at 47 months after MPFL reconstruction using semitendinosus autograft. In their series of 15 MPFL reconstructions, there was one case of bilateral recurrent instability.
- Steiner et al,23 in a series of 34 patients treated with MPFL reconstruction using a variety of graft sources, reported 91.1% good and excellent results at 66 months and no recurrent dislocations.
- In series by both Schottle et al22 and Steiner et al,23 the presence of trochlear dysplasia did not affect the outcome of MPFL reconstruction.
- Nomura and Inoue18 reported on 12 knees after hybrid MPFL reconstruction using semitendinosus graft at a minimum of 3 years follow-up. There were 83% good and excellent results, and no cases of recurrent patellar subluxation or dislocation.

COMPLICATIONS

- Stiffness
- Redislocation
- Excessive medial patellar constraint resulting in a painful, overconstrained patella6,12,16,17
- Patellar fracture

REFERENCES

DEFINITION
- Tibial tubercle transfer is a versatile surgical alternative in the treatment of difficult and resistant patellofemoral disorders ranging from patellofemoral instability to patellofemoral arthritis.
- Patients with combined instability and arthritis often benefit from tibial tubercle transfer.
- Tibial tubercle transfer may be best regarded as “compensatory.” In other words, if a multiplicity of structure and alignment factors leads to patellar instability or arthritis, carefully planned repositioning of the tibial tubercle can compensate for these deficiencies, providing permanent relief of pain and instability.

ANATOMY
- The patella articulates within the femoral trochlea in such a way that the distal aspect of the patella enters the trochlea from a slightly lateralized position upon initiation of knee flexion. Normally the patella enters the trochlea promptly within the first 10 degrees of flexion, first making contact with the distal aspect of the patella.
- As the knee flexes further, load is transferred more proximally on the patella such that in full flexion, contact is on the proximal aspect of the patella. The intervening flexion transfers load more gradually along the patella, moving proximally with each degree of flexion load.¹¹
- As the patella enters the trochlea with further knee flexion, the trochlea becomes deeper, so that containment of the patella is improved. Therefore, in most people, the point of greatest instability is early flexion of the knee, when the trochlea is at its shallowest and containment of the patella is most limited.

PATHOGENESIS
- The pathogenesis of problems around the patellofemoral joint relates to dysplasia of anterior knee anatomy, malalignment, and trauma.
- Most patients with significant dysplasia have a congenital underlying imbalance of the extensor mechanism, which leads to improper morphologic development.

The position of the tibial tuberosity relative to the femoral trochlea further complicates the process of patella entry into the trochlea.⁴
- This relationship has been referred to as the tibial tuberosity to trochlea groove (TT-TG) index, measured in millimeters using superimposed tomographic images of the position of the central trochlea and the tibial tubercle (FIG 1).
- The patella is contained within a soft tissue investing layer of tendon and retinacular structure.
- The lateral retinaculum extends to the iliotibial band but also proximally to the lateral femur and to the tibia (the patellofemoral and patellotibial components, respectively, of the lateral retinaculum).
- On the medial side is the medial patellofemoral ligament (MPFL), which extends from the proximal half of the patella to the adductor tubercle region.¹
- The patellar tendon is located distally, with the quadriceps tendon proximally connecting the patella to the quadriceps muscle. The quadriceps tendon is a massive tendon, including a major vastus lateralis tendon component on the proximal lateral aspect of the patella.
- The superolateral corner of the patella is supported dynamically by the vastus lateralis obliquus, which interdigitates with the lateral intermuscular septum.¹⁴

FIG 1 • The relation of the tibial tubercle (TT) to the central trochlear groove (TG)—the TT-TG relationship—pertains to patella instability. A. Normal TT-TG relationship, in which the tibial tubercle and trochlear groove are lined up. B. Lateralized tibial tubercle.
A chronically lateralized extensor mechanism is likely to cause abnormally high lateral pressure on the femoral trochlea, thereby leading to developmental flattening of the lateral trochlea and also flattening of the patella (FIG 2). Although it is not always the case, this pattern of development most likely explains the poor development of the lateral trochlea and persistent instability in patients with abnormal extensor mechanism alignment. Such patients stretch the medial patella support structure over time, leading to subluxation and tilt of the patella in many cases.

This stretching can lead to chronic instability, chronic overload of the lateral patellofemoral joint, dislocation (which often causes medial patella articular damage), breakdown of the lateral patellofemoral joint, and pain related to overload of the joint and peripatellar retinacula.13

Some patients have anterior knee pain as the result of blunt trauma, usually with the knee flexed.

An impact to the flexed knee and resulting trauma to the patellofemoral joint usually leads to proximal patella injury.

This is important, because anteriorization of the tibial tubercle shifts contact on the patella proximally and can, therefore, exacerbate a lesion on the proximal patella related to blunt injury.

Because movement of the tibial tubercle was not involved in the injury in many patients who have had blunt trauma, the problem usually is not one of abnormal extensor mechanism alignment requiring correction.

NATURAL HISTORY

The natural history of patellofemoral pain, instability, or arthrosis often relates to the imbalance noted earlier. With chronic lateral tracking of the patella in the trochlea, overload occurs with increased point loading on the patella and trochlea, particularly the patella.

Eventually this can lead to breakdown of articular cartilage and what Ficat7 has called excessive lateral pressure syndrome (FIG 3).

Schutzer21 demonstrated a high incidence of patellofemoral tilt and subluxation in patients with patellofemoral pain, compared with controls.

With dislocation of the patella, the medial patellofemoral ligament is torn and, even after healing, elongated. This further exacerbates any tendency toward lateral displacement of the patella out of the trochlea.

With blunt trauma, pain is related to impact and subchondral bone injury, generally on the proximal patella. This pain, then, originates from injured subchondral bone, because there are no nerves in cartilage.

PATIENT HISTORY AND PHYSICAL FINDINGS

With the patient who may be a candidate for tibial tubercle transfer, it is important to establish that this definitive surgery truly is indicated because of a structural alignment imbalance or articular overload condition leading to instability or pain.

The physical examination should emphasize a very critical look at patella tracking within the femoral trochlea, the condition of the medial patellofemoral ligament, evidence of articular breakdown of the patellofemoral joint, evidence of retinacular or soft tissue pain, and a search for other possible causes of pain such as medial or lateral compartment disease or referred pain from the hip or back.

Careful palpation of the retinacular structure around the patella will indicate whether there is soft tissue or retinacular overload contributing to pain.18

In some cases, simple release of the painful retinacular structure may be all that is needed.

When examining the medial patellofemoral ligament, holding the patella laterally in extension is recommended, then slowly...
flexing the knee to see whether the medial patellofemoral ligament delivers the patella into the central trochlea by 20 to 30 degrees of knee flexion. A distinct pressure, pushing the examining finger back as the patella enters the trochlea, should be encountered using this technique.

- If the patella remains lateralized with the examining finger holding it lateral as the knee is flexed to 20 to 30 degrees of flexion, the medial patellofemoral ligament is incompetent.10

- Similarly, in a patient who has had previous extensor mechanism surgery, the examiner should hold the patella medially in extension and flex the knee abruptly to 30 to 40 degrees of flexion (FIG 4).

- If the patella enters the trochlea very suddenly and reproduces the patient’s symptom, he or she actually may have a medial instability problem (ie, medial subluxation) that requires repair or reconstruction of the lateral support structure or even lateralization of the tibial tubercle if it previously was over-medialized.

- The patella is held in the central trochlea, and the knee is flexed with compression of the patella to see if this elicits crepitus or pain. The degree of flexion at which this crepitus or pain occurs is important in localizing the location of the lesion, bearing in mind that the articulation surface of the patella moves proximally as the knee is flexed. This compression of the patella in the trochlea should be repeated as the patient extends the knee actively against resistance of the other examining hand from full flexion up to full extension, taking note of where pain or crepitus occurs with active extension against resistance.

- Every patient should be examined prone so that the hip can be rotated internally and externally to see if there is a source of pain within the hip. With the patient prone, the pelvis is flat, and, therefore, flexion of the knee may be completed to compare with the contralateral side to establish whether the quadriceps and extensor mechanism are overly tight. The patient should be taught at this time how to stretch the extensor mechanism.

- Nonoperative treatment should be exhausted before considering surgical intervention.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- In diagnosis of the anterior knee, a standardized office radiograph with the knee flexed 45 degrees and standardized axial radiograph of the patellofemoral joint with the knee flexed exactly to 30 degrees is very important.15

- By 45 degrees of knee flexion, the patella normally is centralized in the femoral trochlea. This is a good screening test in the office to determine whether there is significant imbalance of the extensor mechanisms.

- Radiographs taken in more than 45 degrees knee flexion are not particularly useful in most patients.

- Our practice has not found 30-60-90-degree radiographs useful.

- Many patients present for evaluation with axial radiographs taken only at 90 degrees of flexion. This probably is easier for radiology technicians, because they can simply hang the patient’s legs over the side of an examining table and take the axial radiograph in this fashion. It is very important to standardize flexion to 45 degrees, using a support frame as needed.

- The other important office radiograph is the true lateral view16 (FIG 5), which is taken with the knee at 30 degrees of flexion and standing. The posterior femoral condyle should be overlapped.

- This view is technically demanding, but most radiology technicians with reasonable experience can palpate the posterior condyles, and with one or sometimes two tries, obtain a good lateral view with overlap (or near-complete overlap) of the posterior condyles.

- This study shows the femoral trochlea completely, so that the central sulcus can be identified as well as both medial and lateral aspects of the trochlea from proximal to distal.

- Other imaging studies include CT, MRI, and radionuclide scan. Relatively few patients require these studies.

- If CT is done, it is best performed at 0, 15, 30, and 45 degrees of knee flexion, obtaining mid-patella transverse images to see how the patella enters the trochlea. This should be done with reproduction of normal standing alignment on the tomographic table.

- MRI is less useful in many patients but can be helpful in evaluating articular cartilage and soft tissue structure, as well as gaining insight into subchondral bone reaction.
Radionuclide scanning is not often used but can be extremely helpful in determining subchondral bone reaction to overload. It may be most applicable in patients with trauma to the anterior knee, unexplained anterior knee pain, or chronic patella overload, and in cases involving workers’ compensation litigation where objective findings beyond the normal studies needed to determine appropriate treatment are particularly important.

In some cases, a single photon emission computed tomographic (SPECT) scan also can help in accurately locating a source of subchondral bone overload. SPECT may play a role, selectively, in patients who require a patella unloading or resurfacing procedure.

Nonoperative Management

Before tibial tubercle transfer is considered, all patients must exhaust nonoperative management, including complete lower extremity core stability therapy, patellofemoral taping and bracing (I prefer the Tru-Pull brace that I helped design, DJ ORTHO, Vista, CA), and modification of activity.

Viscosupplementation may be helpful in some patients with patellofemoral arthritis but has not been very helpful in most cases.

Surgical Management

In patients with more severe extensor mechanism malalignment, instability, pain, and eventual articular cartilage breakdown are fairly common. When specific factors such as disruption of the MPFL cause instability, reconstruction of the deficient structure should be considered first.

In many patients with patella instability, restoration of medial support, either by imbrication (open or arthroscopic) or reconstruction of the medial patellofemoral ligament and release of tight lateral retinaculum, may be the procedure of choice. In general, this is the first line of surgical treatment after failed nonoperative measures in a patient with patella instability related to deficiency of medial support structure.

In patients with more severe dysplasia, a high TT-TG index (see Fig 1B), and degenerative change in the patella or trochlea, tibial tubercle transfer offers an opportunity to improve balance permanently and provide long-term relief of instability.

Tibial tubercle transfer in the treatment of patella instability is best used when the TT-TG index is high (>20 in most cases), the Q angle is high (usually >20 degrees) or the lateral trochlea is dysplastic, such that soft tissue reconstruction alone will either be less likely to succeed or require excessive tension resulting in overload of the medial patellofemoral joint.

Anteriorization alone is best reserved for patients with patella arthritis alone without malalignment.

The primary concern with MPFL reconstruction in the face of more serious malalignment and patella instability is the need to “pull” the patella in a posteromedial direction to gain stability, thereby adding load to the patella that eventually might lead to patellofemoral joint degeneration. For this reason, the wise surgeon will recognize the inherent benefit of tibial tubercle transfer in selected patients with more severe patella instability to compensate for the malalignment problems leading to the instability in a way that limits or avoids point articular loading on the patella.

Tibial tubercle transfer also provides immediate fixation and stability, making early ROM possible, further reducing the risk of stiffness, tightness, and chronic pain in the anterior knee following reconstructive surgery for instability.

In the treatment of patellofemoral arthritis, tibial tubercle transfer plays an important role in joint preservation.

Many patients have patellofemoral arthritis as a result of excessive lateral pressure, as originally described by Ficat. This excessive lateral pressure eventually causes erosion of the lateral patellofemoral joint, sometimes to bone, because of the constant lateralization of the patella related to lateral subluxation and high lateral pressure on the lateral patella facet. Lateral release has been used to reduce some of this pressure and is helpful in the early stages when patella tilt is prominent.

Tibial tubercle transfer is a powerful procedure for unloading and rebalancing the extensor mechanism, however, placing the patella into the center trochlea and maintaining it there through a range of motion.

By adding some anteriorization to a medial tibial tubercle transfer (ie, anteromedial tibial tubercle transfer) the distal articular surface of the patella also may be unloaded. This is important, because many patients with patellofemoral chondrosis or arthrosis have distal patella articular breakdown or pain. Anteriorization of the tibial tubercle unloads the distal articular surface of the patella permanently, and the medialization component of this procedure rebalances the patella in the central trochlea, unloading the lateral facet.

Most patients with chronic lateralization of the extensor mechanism develop lateral facet breakdown and distal patella degeneration over time because of the abnormal shear stress and lateral overload. Anteromedial tibial tubercle transfer compensates for this and is, therefore, the procedure of choice for treating articular degeneration and pain emanating from the distal or lateral patella articular surface.

Anterolateral tibial tubercle transfer may be best regarded as a salvage procedure in patients who have had previous overmedialization of the tibial tubercle. It has been helpful in relieving pain related to chronic medial patellofemoral arthritis resulting from a previous Hauser procedure in which the tibial tubercle was moved posteriorly, medially, and distally to stabilize the extensor mechanism at an earlier time.

Medial Tibial Tubercle Transfer

Incision and Dissection

Medial tibial tubercle transfer is best approached through a midline incision from the mid patella to a region approximately 5 to 7 cm distal to the tibial tubercle.

The medial and lateral borders of the patella tendon are identified, the anterior tibialis muscle is reflected posteriorly and retracted, the skin edges are retracted, and a cut is made deep to the tibial tubercle.

Osteotomy

A flat incision is made posterior to the tibial tubercle, tapered anteriorly at its distal extent such that only about 1 mm of bone is left at the distal tip of the osteotomy and the proximal cut is made about 2 mm above the patellar tendon insertion.

This cut should be made perpendicular to the anterior surface of the tibia such that a flat ledge is left to add
additional stability to the transferred tibial tubercle. This proximal cut must be made in such a way that the tibial tubercle may be freely moved medially, i.e., so that the medial side of the proximal cut is more proximal than the lateral side of the proximal cut, open medially.

- The thickness of the cut deep to the tibial tubercle will vary depending on the individual patient’s need for medialization.
- In patients with a severe dysplasia requiring more than 1 cm of medialization, a deeper cut will be required.
- In patients requiring 1 cm of medialization, a proximal tibial tubercle thickness of 1 to 1.5 cm is ample in most cases.
- Care must be taken to taper this osteotomy anteriorly at the distal extent of the cut to allow for easy green-stick fracturing of the tip of the osteotomy to move the tubercle medially.

Completion of the Transfer

- After the osteotomy has been completed with an oscillating saw, the proximal cut usually is made with a ½-inch osteotome.
- The osteotomized fragment is elevated and then displaced medially. If there is an overhang of bone medially, it can be removed with the saw or a rongeur.
- The fragment is then stabilized securely with two cortical lag screws (TECH FIG 1), carefully measuring the depth of the drill hole, overdrilling the proximal fragment, and lagging the fragment down using the posterior cortex to hold the cortical screw.
- Care must be taken not to allow the cortical screw tip to protrude any more than necessary beyond the posterior cortex.

ANTEROMEDIAL TIBIAL TUBERCLE TRANSFER

Incision and Dissection

- To unload both the distal and lateral aspects of the patella, an oblique osteotomy must be created deep to the tibial tubercle, and the tibial tubercle transferred in both anterior and medial directions.8,12
- To perform anteromedial tibial tubercle transfer, a longitudinal incision close to midline, extending from a region about halfway between the patella and the tibial tubercle to about 7 cm distal to the tibial tubercle usually is sufficient.
- After isolating the patellar tendon, the anterior tibialis muscle is released and reflected posteriorly.
- Because an oblique osteotomy will be made from medial to lateral, a large retractor must be placed to retract the anterior tibialis muscle laterally to view the saw making the osteotomy cut as it exits on the posterolateral aspect of the tibia. The entire lateral side of the tibia must be under direct view11 (TECH FIG 2).

Osteotomy

- At this point, it usually is best to use a guide, such as the Tracker guide (Mitek, Norwood, MA), to ensure an accurate osteotomy cut. With experience, some surgeons can
TECH FIG 3 • A. Displacement of the tibial tubercle transfer showing planes for cuts. B. For anteromedial tibial tubercle transfer, the cut proceeds obliquely from medial to lateral, tapering toward the anterior crest distally. After transferring the tibial tubercle along the osteotomy (C), both anteriorization and medialization of the tibial tubercle are achieved (D).

- make this cut without a guide, but only a surgeon who is doing this type of surgery on a regular basis will feel comfortable without guide control.
- An external fixator block also may be used to create an appropriate orientation for the osteotomy (TECH FIG 3A). A drill bit is left at the top and bottom of the osteotomy.
- The osteotomy usually extends from the level of the tibial tubercle to a level of about 7 to 9 cm distally on the tibia and again must exit at the level of the anterior cortex of the tibia to avoid a large fragment distally.
  - Making a deep cut distally increases the risk of tibia fracture; this should be avoided.
- After the guide is placed at the desired angle to create an oblique osteotomy from medial to lateral, a cut is made from the region immediately adjacent to the patellar tendon insertion medially and angled posterolaterally so that the saw blade will exit on the lateral cortex (TECH FIG 3B).
  - This strategy avoids injury to the anterior tibial artery and deep peroneal nerve, which are around the posterolateral corner of the tibia posteriorly.
  - The cut should start distally first where it is most visible, and as the oblique cut proceeds proximally, it will become more posterior.
  - Once the proximal extent of the cut has reached the level of the mid to posterior portion of the lateral tibia cortex, it should be stopped at the lateral side. An osteotome or saw then is used to make a back cut from the corner of the proximal lateral corner of the osteotomy up to a point proximal to the patellar tendon laterally.
  - This allows for release of the lateral cortex when the osteotomy has been completed, and the osteotomized fragment will be displaced anteromedially.
- The third cut for anteromedial tibial tubercle transfer is directly proximal to the patellar tendon insertion on the tibia, about 2 mm above the patellar tendon insertion.
  - This cut usually is made with a ¼- or ½-inch osteotome under direct vision using an Army-Navy retractor to hold the patellar tendon anteriorly.
  - It is best made from medial to lateral and connects the proximal extent of the medial osteotomy cut to the oblique back cut on the lateral side so that the osteotomy is now free to displace anteromedially.
  - It is moved anteromedially by greenstick fracturing the anterior cortex distally, which should be no more than 1 to 2 mm thick at its distal extent.
  - The osteotomized fragment is moved about 1 cm but may be moved slightly more, as needed, to achieve more anteriorization or medialization.
PEARLS AND PITFALLS

**Avoiding complications**

- Patients should stay on crutches for at least 6 weeks, because fracture is a risk with weight bearing that is too aggressive.
- Smoking should be stopped before surgery and not resumed for at least 2 months because of its adverse effect on bone healing.
- Surgery should be accurate and fixation secure.
- Patients should start ROM very soon after surgery to avoid stiffness.
- All patients should receive some form of postoperative anticoagulation, and should have prophylactic antibiotics at the time of surgery.
- Hemostasis should be meticulous, and proper drainage of hematoma implemented as needed.

POSTOPERATIVE CARE

- Following tibial tubercle transfer, immediate ROM is important.
  - If stability is secure, patients are started immediately on ROM exercises.
  - These may start with a single cycle of flexion a day if proximal reconstruction has been done and there is concern about stretching out a proximal repair.
  - In such cases, a short period of immobilization in extension may be appropriate for soft tissue healing, but a single cycle of knee flexion daily after the first 10 to 12 days is important to ensure full ROM later and maximal ROM ultimately.
- Patients are kept on crutches for 6 to 8 weeks and resume weight bearing as tolerated after 6 weeks.
- During the initial 6 weeks, we recommend toe-touch or light weight bearing on the affected side.
- We recommend anticoagulation with aspirin for at least 4 to 6 weeks for most patients.
- Most of our patients go home from same-day surgery and are seen in 1 to 3 days as needed and then for suture removal and radiographs at 10 to 12 days.
- Steri-strips are applied and kept in place for 4 to 6 weeks to minimize wound spread.

COMPLICATIONS

- The primary concerns following tibial tubercle transfer are fracture of the tibia,22 stiffness, thrombophlebitis, nonunion, infection, and hematoma.
- These complications usually can be avoided with proper care.
- Gross obesity increases the risk of complications.

OUTCOMES

- Buuck2 reviewed the results of anteromedial tibial tubercle transfer in patients 4 to 12 years following the procedure and demonstrated that good results are maintained over time.
- Our follow-up studies have consistently revealed a satisfactory outcome in 85% to 90% of patients. Pidorianet al17
demonstrated that results are closely related to the location of articular lesions. Patients with lateral and distal patellar lesions are more likely to experience relief than patients with proximal (dashboard) or medial (s/p dislocation) lesions.

REFERENCES
DEFINITION
- Compartment syndrome can be either acute or chronic.
- Acute compartment syndrome usually is due to trauma to, or reperfusion of, the extremity. Chronic exertional compartment syndrome (CECS) often is associated with the repetitive loading or microtrauma of endurance activities.
- Both acute and chronic compartment syndromes are due to increased interstitial pressure within a compartment, resulting in decreased perfusion and ischemia of soft tissues.
- In contrast to the reversible nature of CECS, acute compartment syndromes progress rapidly and require urgent fasciotomy to avoid irreversible soft tissue necrosis in the affected compartment.
- Wilson first described the concept of CECS in 1912, but Mavor\textsuperscript{12} was the first to successfully treat a patient with anterior compartment syndrome of the leg using a fasciotomy.
- Clinical manifestations of exercise-induced pain relieved by rest, swelling, numbness, and weakness of the extremity have long been attributed to elevated intracompartmental pressures.\textsuperscript{5,17}

ANATOMY
- The leg contains four compartments: anterior, lateral, superficial posterior, and deep posterior (FIG 1).
- The anterior compartment contains the anterior tibial artery, the deep peroneal nerve, and four muscles (tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius). Its borders are the tibia, fibula, interosseous membrane, anterior intermuscular septum, and deep fascia of the leg.
The lateral compartment contains the superficial peroneal nerve and two muscles (peroneus longus and peroneus brevis).

The common peroneal nerve branches into the superficial and deep peroneal nerves within the substance of the peroneus longus after passing along the neck of the fibula.

The superficial peroneal nerve continues within the lateral compartment, while the deep peroneal nerve wraps around the fibula deep to the extensor digitorum longus until reaching the anterior surface of the interosseous membrane.

The lateral compartment does not contain a large artery; the peroneal muscles receive their blood supply via several branches of the peroneal artery.

The lateral compartment is bordered by the anterior intermuscular septum, the fibula, the posterior intermuscular septum, and the deep fascia.

The superficial posterior compartment contains the sural nerve and three muscles (gastrocnemius, soleus, and plantaris) and is surrounded by the deep fascia of the leg.

The deep posterior compartment contains the posterior tibial and peroneal arteries, tibial nerve, and four muscles (flexor digitorum longus, flexor hallucis longus, popliteus, and tibialis posterior).

It is bordered anteriorly by the tibia, fibula, and interosseous membrane, and posteriorly by the deep transverse fascia.

A fifth compartment that encloses the tibialis posterior muscle has been described, but its existence is controversial. It has been suggested that the presence of an extensive fibular origin of the flexor digitorum longus muscle may create a sub-compartment within the deep posterior compartment that may develop elevated pressures.

**PATHOGENESIS**

The etiology of CECS is not entirely understood. It is thought to be due to an abnormal increase in intramuscular pressure during exercise resulting in impaired local perfusion, tissue ischemia, and pain.

Contributing factors may include exertion-induced swelling of the muscle fibers, increased perfusion volume, and increased interstitial fluid volume within a constrictive compartment.

The elevated intramuscular pressure decreases arteriolar blood flow and diminishes venous return.

This, in turn, results in tissue ischemia and accumulation of metabolites.

Elevated lactate levels and water content have been documented in muscle biopsies from compartments with elevated pressures following exercise.

Muscle hypertrophy and increased perfusion volume with exertion do not explain the elevated resting pressure seen in patients with CECS, however. The mechanical damage theory hypothesizes that heavy exertion results in myofibril damage, release of protein-bound ions, increased osmotic pressure in the interstitial space, and, therefore, decreased arteriolar flow in the compartment.

Additionally, in some cases focal fascial defects may be a contributing factor.

Anterolateral fascial hernias are present in 39% to 46% of patients with CECS, as compared to less than 5% of asymptomatic individuals.

**NATURAL HISTORY**

CECS of the leg is a common injury in people involved in running and endurance sport activities, such as young athletes and military personnel.

Pain, as well as occasional numbness and weakness, develops at a predictable interval after initiation of a repetitive, endurance type activity and resolves with rest.

The symptoms are longstanding and recurrent, because patients tend to self-limit but then subsequently attempt to resume activities.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

The following symptoms may be present upon exertion and resolve with rest:

- A sensation of cramping, burning, aching, or tightness in the region of the affected compartment(s)
- Numbness or weakness in the extremity
- A transient footdrop may develop if the deep peroneal nerve is affected.
• A temporary loss of eversion strength may occur if the superficial peroneal nerve is affected.
• Physical examination of the resting lower extremity often is unremarkable.
• Examination following exercise may reveal:
  • Increased tightness of the involved compartments
  • If a fascial defect is present, a focal area of tenderness and swelling may develop as the underlying muscle bulges through the defect.
  • A positive Tinel’s sign over the defect if the superficial peroneal nerve is compressed
• When the history and physical examination findings are consistent with CECS, the diagnosis should be confirmed with pre- and postexercise compartment pressure measurements.
• Most clinicians follow the diagnostic criteria of Pedowitz et al, in which a resting pressure greater than or equal to 15 mm Hg or a 1-minute postexercise measurement greater than or equal to 30 mm Hg or a 5-minute postexercise measurement greater than or equal to 20 mm Hg is considered abnormal and diagnostic of CECS.
• The exercise performed at the time of testing must be intense enough to reproduce the patient’s symptoms; otherwise, the postexercise pressure measurements may be falsely low.
• Several methods for measuring compartment pressures have been described in the literature.
  • These include the slit catheter, wick catheter, needle manometry, digital pressure monitor, microcapillary infusion, and solid-state transducer intracompartmental catheter methods.
  • The Stryker intracompartmental pressure monitor (Kalamazoo, MI) is a handheld digital monitor that can be used to check multiple compartments. It can be used with a side port needle or with an indwelling slit catheter to obtain serial measurements in a single compartment.
  • A new handheld digital device recently developed by Synthes (Paoli, PA) also allows placement of indwelling catheters and may be useful for obtaining serial measurements.
• Near-infrared spectroscopy has been used to determine tissue oxygen saturation. This may be a noninvasive, painless alternative to intracompartmental pressures in the diagnosis of CECS, but is not currently standardized or readily available.
• The vibration test consists of placing a vibrating tuning fork over bone at the area of suspected stress; an elicitation of pain is consistent with a stress fracture.
• Pain when performing resisted ankle dorsiflexion and inversion is consistent with tibialis posterior tendinitis or posteromedial periostitis.

IMAGING AND OTHER DIAGNOSTIC STUDIES
• When pressure measurements are not consistent with CECS, further diagnostic studies may be necessary to explore the differential diagnosis.
• Plain radiographs may demonstrate a periosteal reaction in patients with tibial stress fractures or posteromedial tibial periostitis.
• Bone scan will show increased uptake, and MRI may show edema or a black line at the site of a stress fracture.
• Tingling, numbness, or a positive Tinel’s sign at a specific location may warrant an EMG and nerve conduction study to evaluate for peripheral nerve entrapment.

DIFFERENTIAL DIAGNOSIS
• Tibial stress fractures
• Posteromedial tibial periostitis
• Tenosynovitis of posterior tibialis or ankle dorsiflexors
• Peripheral nerve entrapment
• Radiculopathy secondary to lumbar pathology
• Complex regional pain syndrome
• Peripheral vascular disease
• Popliteal artery entrapment syndrome
• Deep venous thrombosis

NONOPERATIVE MANAGEMENT
• Nonoperative management usually requires activity limitation.
• Symptoms usually return with resumption of prior activity level. Surgery, therefore is indicated in patients who cannot tolerate activity restriction.

SURGICAL MANAGEMENT
• Surgical treatment involves fasciotomy of the affected compartments, sometimes with partial fasciectomy.
• Patients who are unable to maintain their desired activity level owing to symptoms of CECS are appropriate operative candidates.

Preoperative Planning
• It is critical to identify which compartments are affected.
  • All symptomatic compartments should be addressed at the time of surgery. It is common for a failed index procedure to be due to a failure to release an affected compartment.
  • The appropriate approach should be selected based on the compartments that need to be released.

Positioning
• The patient is placed in the supine position for each technique.

Approach
• A single- or dual-incision technique can be used to release the lateral and anterior compartments.
• The perifibular approach can be used to access all four compartments.
• A second posteromedial approach offers easier access to the superficial and deep posterior compartments.
• Endoscopically assisted fasciotomies allow access to the entire length of the compartment, allow visualization of fascial hernias, and may minimize surgical complications such as postsurgical fibrosis and injury to the superficial peroneal nerve.
• The safety and effectiveness of endoscopically assisted compartment release has been demonstrated in cadavers.
• A technique using balloon dissectors and carbon dioxide insufflation is described in the Technique section.
SINGLE-INCISION LATERAL APPROACH FOR ANTERIOR AND LATERAL COMPARTMENT FASCIOTOMY

- The patient is placed in the supine position on the operating table.
- A 5-cm vertical incision is made halfway between the fibular shaft and the tibial crest at the midportion of the leg. The incision should lie over the anterolateral intermuscular septum (TECH FIG 1A).
  - If a focal fascial defect is present, the incision should be adjusted so that the defect can be incorporated.
- A small transverse incision is made just through the fascia, and the septum and the superficial peroneal nerve, which lie near the septum in the lateral compartment and exit the fascia near the distal aspect of the incision, are identified (TECH FIG 1B).
- Longitudinal releases of the anterior and lateral compartments are performed using long Metzenbaum scissors in a proximal and distal direction from the transverse incision in the fascia that crosses over the anterolateral intermuscular septum (TECH FIG 1C).
- A partial fasciectomy may be performed, particularly in cases of recurrence following a prior fasciotomy.
- The fascia is left open.
- The subcutaneous tissue is approximated using 2-0 absorbable suture material.
- The skin is closed with a running subcuticular 4-0 nonabsorbable suture material and Steri-strips.

DUAL INCISION LATERAL APPROACH FOR ANTERIOR AND LATERAL COMPARTMENT FASCIOTOMY

- The patient is placed in a supine position.
- The leg is divided into thirds, and two 3-cm incisions are placed at the junction of the thirds over the anterolateral intermuscular septum (TECH FIG 2A,B).
- The superficial peroneal nerve is identified as it exits the fascia near the distal incision (TECH FIG 2C).
- Fasciotomies of the anterior and lateral compartments are performed on each side of the intermuscular septum (TECH FIG 2D).
- The incisions in the fascia are connected using Metzenbaum scissors to divide the fascia from the proximal incision toward the knee (TECH FIG 2E), then from
TECH FIG 2 • Dual-incision approach. **A.** The leg is visually split into thirds, and two 3-cm incisions are placed at the junction of the thirds over the anterolateral intermuscular septum. **B.** The superficial peroneal nerve is located 10 to 12 cm proximal to the tip of the lateral malleolus. The inferior incision is centered over this area. **C.** Dissection of the superficial peroneal nerve. **D.** A fascial defect often is present in this area, and compartment releases should be centered over these areas if possible. **E.** The incisions in the fascia are connected using Metzenbaum scissors to divide the fascia. **F.** Long scissors are used and are opened only slightly at the tips. (B–D, F: Courtesy of Mark D. Miller, MD.)

the proximal incision toward the distal incision, and finally from the distal incision toward the ankle (TECH FIG 2F).

- Distally, the fasciotomy should extend to 4 to 6 cm proximal to the ankle.
- At the distal aspect of the anterior compartment, the release should be directed more toward the midline to minimize risk of injuring cutaneous sensory nerves at the lateral aspect of the compartment.

- The distal aspect of the lateral compartment fasciotomy should be directed more laterally.
- The subcutaneous tissue is closed with 2-0 absorbable suture material.
- The skin is closed with running subcuticular 4-0 sutures and Steri-strips.

PERIFIBULAR APPROACH FOR FOUR-COMPARTMENT FASCIOTOMY

- The patient is placed in the supine position.
- A 10-cm incision is made directly over the midportion of the fibula (TECH FIG 3A).
- The skin is retracted anteriorly and the fascia of the anterior and lateral compartments is released longitudinally in a proximal and distal direction (TECH FIG 3B).
- The skin is retracted posteriorly.
- The fascia overlying the lateral head of the gastrocnemius is released.
- The fascia over the superficial posterior compartment is incised for a distance of about 15 cm.
The anterior and lateral compartments are retracted anteriorly and the superficial posterior compartment posteriorly. The soleal bridge must be released from the fibula (TECH FIG 3C).

The fascia over the flexor hallucis longus is identified and incised.

The gastrocnemius is retracted posteriorly and the flexor hallucis longus laterally to expose the posterior tibial artery, tibial nerve, and peroneal artery overlying the tibialis posterior.

The fascia is incised around the tibialis posterior and the interval between the muscle and the origins of the flexor hallucis longus is widened if it is constrictive.

The subcutaneous tissue is approximated with 2-0 absorbable suture.

The skin is closed with running subcuticular nonabsorbable 4-0 suture.

---

**POSTEROMEDIAL INCISION FOR FASCIOTOMY OF THE POSTERIOR COMPARTMENTS**

A vertical incision 8 to 10 cm in length is made over the midportion of the leg approximately 1 cm posterior to the posteromedial edge of the tibia (TECH FIG 4A).

The saphenous vein and nerve are identified in the subcutaneous tissue and retracted anteriorly.

The fascia over the superficial posterior compartment is incised for a distance of about 15 cm (TECH FIG 4B, C).

To fully access the deep posterior compartment, the origin of the soleus from the proximal tibia and fibula must be detached (TECH FIG 4D).

The deep fascia can then be sharply divided with Metzenbaum scissors (TECH FIG 4E–G).

The fasciotomy should extend distally to 8 to 10 cm above the ankle.

The opening between the origins of the flexor hallucis longus and the tibialis posterior is enlarged if constrictive.

The subcutaneous tissue is closed with 2-0 absorbable suture.

The skin is closed with running subcuticular nonabsorbable 4-0 suture.
ENDOSCOPICALLY ASSISTED COMPARTMENT RELEASE

- The patient is placed in a supine position.
- Balloon dissectors can be used to create an optical cavity at the fascial cleft, which is the potential space between the superficial fascia (the deepest layer of the skin and subcutaneous tissue) and the deep fascia (the fascia overlying a muscle compartment; TECH FIG 5).
- To insert the balloon dissector, a 2-cm transverse incision is made either at the anterolateral aspect of the knee between the fibular head and Gerdy’s tubercle or at the posteromedial aspect of the knee at the level of the tibial crest.
- Dissection is carried down through the subcutaneous fat and superficial fascia until the deep fascia overlying the muscle is visualized.
- The balloon dissector with a sheath around it is inserted between the superficial and deep fascial layers under direct observation and manual palpation to the level of the ankle.
- The sheath is removed and the balloon is inflated to create a cavity within the fascial cleft.
- The balloon is then deflated and removed.
- A one-way cone-shaped cannula is inserted in the skin at the site of balloon insertion.
- The optical cavity between the superficial and deep fascial layers can be maintained subsequently with 15 mm Hg of carbon dioxide insufflation to allow adequate visualization of the fascia to be released and to allow adequate space to perform soft tissue dissection with the endoscopic equipment.
Alternatively, the cavity is not insufflated, but is maintained with towel clips externally.

Next, the fascia is released with endoscopic scissors down to the level of the ankle under direct vision.

If necessary, a distal instrument portal with a pneumatic lock can be placed, but the fasciotomies usually are carried out proximal to distal through the initial portal.

After the release, the cannula is removed and the cavity is deflated.

The wound is closed in a two-layer fashion with 2-0 Vicryl for the deep layer and a running subcuticular stitch for the skin over a medium Hemovac drain.

---

**PEARLS AND PITFALLS**

| Superficial peroneal nerve injury | Identify the nerve as it exits the fascia at the junction of the distal and middle thirds of the leg; direct the anterior fasciotomy medially and the lateral fasciotomy posteriorly at the distal extent. |
| Saphenous vein and nerve injury | Identify the structures in the subcutaneous tissue at the medial aspect of the leg. Avoid excessive traction on the saphenous nerve, which results in a traction paresthesia. |
| Incomplete fascial release | Muscle herniates at the bottom of the “V” of the fasciotomy, resulting in pain. Extend lateral and anterior fasciotomies to 4 to 6 cm above the ankle and posterior fasciotomies to 8 to 10 cm above the ankle. |

**POSTOPERATIVE CARE**

- Active range of motion at the ankle and knee should begin immediately.
- Crutches can be used as needed in the initial postoperative period, but patients are encouraged to bear weight as tolerated and perform light activities.
- Elevation of the legs while at rest may help to decrease pain and swelling.
- Full activity usually can be resumed 4 to 6 weeks after surgery.

**OUTCOMES**

- Various techniques of compartment release have reports of success rates ranging from 81% to 100%.
  - These techniques include open fasciotomies, one- or two-incision minimally invasive subcutaneous fasciotomies, and fasciotomies with partial fasciectomy.
  - Adequate long-term follow-up is lacking in the literature.
  - Slimmon et al reported on long-term follow-up of patients treated with fasciotomy with partial fasciectomy and noted a good or excellent outcome in 60% at a mean follow-up of 51 months. Thirteen of 62 had reduced activity levels due to recurrence of symptoms or development of a different lower extremity compartment syndrome.
  - Fasciotomy appears to be less effective in alleviating pain in the deep posterior compartment than in other compartments.
  - Some authors have postulated that failure of the fasciotomy may be due to an incomplete fasciotomy or not identifying and releasing the fascia around the tibialis posterior.
- Recurrence rates of 3% to 17% have been reported after fasciotomy.
  - Recurrence may be due to a number of factors, including inadequate fascial releases, failure to decompress a compartment that was believed to be asymptomatic, nerve compression by an unrecognized fascial hernia, and the development of proliferative scar tissue.
  - Other reported complications of fasciotomies with some degree of subcutaneous or blind dissection include arterial injury, hematoma or seroma formation, superficial wound infections, peripheral cutaneous nerve injuries, and deep venous thromboses.
  - The superficial peroneal nerve is particularly vulnerable as it exits the fascia over the lateral aspect of the leg at the junction of the middle and distal thirds.

BACKGROUND

- Care of peripheral nerve problems requires knowledge and understanding of nerve pathology, anatomic nerve variations, patterns of nerve damage and entrapment that follow trauma and common operative procedures, and specialized surgical techniques for manipulation of the damaged peripheral nerve.
- Unlike other surgical disciplines, a large proportion of peripheral nerve surgery attempts to correct neuropathy in the postoperative patient and, therefore, is reoperative in nature.
- Lateral femoral cutaneous nerve (LFCN) neuropathy can be encountered in the orthopedic patient after injuries or procedures in proximity to the anterior superior iliac spine (ASIS), the inguinal region, or the anterior thigh.
  - The symptoms are limited to pain or paresthesias in the distribution shown in FIGURE 1, because this nerve carries only sensory signals.
  - Surgical procedures and trauma to the lateral knee both represent potential for common peroneal nerve (CPN) injury.
  - The nerve can become entrapped in postoperative scar tissue, stretched with knee or ankle dislocations, or inadvertently directly damaged, resulting in neuropathy.

ANATOMY

Lateral Femoral Cutaneous Nerve

- The LFCN arises from the lumbar plexus through contributions from the dorsal divisions of the L2 and L3 spinal roots. In most people, the nerve courses medial to the ASIS and traverses the groin crease under the inguinal ligament as it descends to innervate the thigh.
- The nerve is prone to iatrogenic injury when its anatomy is aberrant; the surgeon should be aware that the LFCN can run through the inguinal ligament and against the ASIS or over the most medial portion of ASIS rather than in its usual course.
- The surface anatomy and the most common site of impingement can be seen in FIGURE 2.

Common Peroneal Nerve

- The CPN is a branch of the sciatic nerve, formed from contributions from the sacral plexus from L4 to S2.
- Pathology of the CPN classically is seen as it wraps around the neck of the fibula, deep to the peroneus longus muscle just before it splits into its deep and superficial branches (FIG 3).
- The CPN innervates the muscles for foot dorsiflexion and eversion and provides sensory innervation to the anterolateral lower leg and the majority of the dorsum of foot and toes.

General Nerve Anatomy

- The peripheral nerve has a significant intrinsic blood supply that permits the surgeon to lift the nerve from its anatomic bed, open the epineurium, and operate between the fascicles.¹
- The endoneurial and perineurial microvessels maintain excellent vascularity to the peripheral nerve. Segmental blood vessels enter the peripheral nerve through the mesoneurium. In addition, an extensive number of longitudinal vessels in the epineurium, perineurium, and endoneurium supply the nerve.²
- Maki et al³ have demonstrated that the “safe” length a nerve can be elevated from its bed (its segmental vascular supply) is a distance of about 60 times the diameter of the nerve. Therefore, the surgeon should consider primarily the need to move the nerve into an area that is free from forces that might externally compress it and, thus, cause symptomatic neuropathy but also should acknowledge internal
Peripheral nerve surgery encompasses repair of two common pathophysiologic entities:

- Accidental nerve transection or direct crush injury leads to nerve dysfunction and possible painful neuroma formation.
- Scar formation from any surgery or trauma can engulf a peripheral nerve and compress it; symptomatic relief can then be accomplished through surgical decompression of the peripheral nerve.

Peripheral nerve injury becomes symptomatic either when a critical function is lost or when paresthesia and pain replace normal sensory signaling.

- Partial or complete nerve transection causes loss of sensory or motor function because of loss of nerve continuity or disruption of the nerve’s blood supply. The nerve’s regenerative capacity then either re-establishes neuronal continuity or forms a disorganized scar within a mature end-bulb neuroma.
- Similarly, compression on a peripheral nerve causes ischemia and neuroma formation.1
- A neuroma contains bundled, disorganized nerve endings within a collagenous mass, and is an anatomic source of the localized pain and paresthesia following peripheral nerve damage.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- History and physical examination, particularly a thorough neurologic examination, often suggest the diagnosis by demonstrating a dermatomal distribution of pain or paresthesia. Further imaging and electrodiagnostic testing may be necessary, mainly to evaluate other causes for the symptoms.2,4
- Central nervous system disease, particularly spinal root impingement, shares many of the same symptoms and must be excluded.
- Diagnostic workup must evaluate and exclude other etiologies for postoperative pain, particularly infection, loosened hardware, mechanical misalignment, spinal involvement, and neoplasm.
- The timing of the sensory or motor symptoms needs to be considered when taking the history and performing the physical examination, because that can aid in understanding the cause of neuropathy.
- When encountering potential neuropathies in the knee or lower leg, the clinician must consider that, although the common peroneal nerve is the major peripheral nerve affected following knee surgery, neuromas of sensory nerves supplying the knee and its surroundings may develop when they are severed or encased in scar tissue.
- These smaller peripheral nerves can be the source of chronic postoperative knee pain and can be mistaken for CPN neuropathy or mask the CPN involvement.
- Therefore, the examining physician should be aware of the different possible causes of pain in this anatomic area and should be able to distinguish deep and superficial paresthesias and pains in the knee area.
- The most commonly affected sensory nerves involved in deep knee pain are the lateral retinacular nerve, the medial retinacular nerves, and the articular branch of the common peroneal nerve, whereas superficial knee pain is caused mainly by involvement of the infrapatellar branch of the saphenous nerve and the medial and anterior cutaneous nerves of the thigh.

**FIG 3** Anatomy of the common peroneal nerve. Note the proximity of the nerve to the fibula as it wraps anteriorly on the lower leg.
If any of these smaller nerves is suspected as the cause of a patient’s symptoms, referral to a peripheral nerve surgeon is suggested.

**IMAGING AND DIAGNOSTIC STUDIES**

- Current imaging techniques—including CT, MRI, and radiolabeled bone scans—have limited, if any, value confirming the diagnosis of a malfunctioning nerve.
- Electrodiagnostic studies also can have a false-negative rate as high as 33%, whereas nerve blocks, because of anatomic variations, can give a false-negative result.
- For these reasons, it cannot be overstated that a diagnostic workup must be interpreted cautiously.

**NONOPERATIVE MANAGEMENT**

- Medical management of paresthesias and pain from injured peripheral nerves centers on symptom management:
  - Activity and lifestyle modification
  - Narcotic and nonnarcotic analgesics
  - Centrally acting agents such as gabapentin and pregabalin
  - Nerve blocks
  - Physical and occupational therapy
- Although medical management offers temporary relief in most patients, it can be complicated by increasing dosage requirements and narcotic dependence, as an acute insult develops into a chronic pain syndrome.
- Among the first steps to focus on are eliminating possible causes of neuropathy and optimizing the patient’s medical condition if comorbidities are present.
- Nonoperative management is considered a failure when patients with neuropathy do not achieve a reasonable recovery by approximately 12 weeks.
  - At that point, additional evaluation by a peripheral nerve surgeon or electrodiagnostic workup is appropriate to determine whether surgical intervention or continued observation is indicated.

**LATERAL FEMORAL CUTANEOUS NERVE**

- The patient is placed in the supine position, and an incision of about 6 cm is made anterior to the anterior superior iliac spine, extending toward the thigh.
- Careful dissection is then carried to deep fascia and toward the inguinal ligament (**TECH FIG 1A**).
- The use of loupe magnification as well as proper microsurgical instruments and bipolar electrocautery is essential when identifying the LFCN because of the variability in its anatomy (**TECH FIG 1B**).
- The LFCN could be encountered at any point in the dissection of the inguinal ligament and must not be damaged.
- Once identified, the nerve is first decompressed distally approximately 4 to 6 cm and then proximally at the inguinal ligament and internal oblique and transversalis deep muscle fascia, where most compression typically occurs (**TECH FIG 1C**).
  - After this release, retroperitoneal decompression is performed by retraction of the muscle and excision of the deep fascia sitting on the top of the nerve (**TECH FIG 1D,E**).
  - Great caution must be exercised dissecting in this area because of the proximity of the deep circumflex iliac artery that crosses the nerve in the retroperitoneum.

**TECH FIG 1**

A. Exposure for dissection of the lateral femoral cutaneous nerve (LFCN). B. Identification of LFCN. C. Internal oblique muscle elevated off LFCN at compression site. D,E. LFCN proximally and distally decompressed. Note the cuff of internal oblique that has been removed around the LFCN proximally.
COMMON PERONEAL NERVE

- With the patient in a supine position, a thigh tourniquet is placed—as long as the patient does not have previous vascular bypasses in this area—and an incision is made 1 to 2 fingerbreadths below the fibular head (TECH FIG 2A).
- Dissection is carried to the deep fascia under loupe magnification, because proper identification of the nerve is critical (TECH FIG 2B).
  - The nerve can easily be mistaken for yellow fat, particularly if it runs abnormally superficially or was displaced with trauma.
- Proximal decompression is performed first by release of the gastrocnemius fascia and its attachment to hamstring and iliotibial fascial tissues (TECH FIG 2C).
- Distal dissection is performed by incising the peroneus longus fascia and retracting this muscle laterally.
- A fascial band that causes both a kink in the nerve as well as compression against the fibula can then be visualized and addressed (TECH FIG 2D).
- Closure is then performed in anatomic layers, sparing the deep fascia, which is not closed, to avoid recreating the nerve compression.
- Great caution should be exercised in patients with a history of previous knee trauma or dislocation, because the anatomy of the nerve may be aberrant, which could lead to iatrogenic nerve injury during surgical approach and manipulation.

TECH FIG 2 • A. Schematic for skin incision to access the common peroneal nerve. B. Exposure of CPN through surgical incision. C. Identification of CPN. D. Identification of compressive band of peroneus longus muscle fascia over CPN.
**POSTOPERATIVE CARE**

- Wound healing concepts should be applied to the peripheral nerve.
  - During the first week after surgery, the nerve will lie in an environment that is predominantly inflammatory. Collagen is not deposited into the wound until the second week, and cross-linking of the collagen does not occur until after the third week.
  - If the nerve is kept immobile during the second and third postoperative weeks, it will become adherent to the surrounding tissues.
  - Conversely, for the nerve to be loose and able to slide through its surrounding tissues, it is necessary to allow the nerve to move with respect to its bed following the first week of splinting.
  - The fact that a nerve will not adhere to a bed of cut muscle and fibrous tissue if it is allowed to glide early in the postoperative period was demonstrated for the ulnar nerve at the elbow in a baboon model.\(^7\)
  - Therefore, in operation on the peripheral nerve, it is essential that the postoperative regimen include some movement of the joints during the first week and splinting be reserved mainly for cases involving nerve grafting.

DEFINITION
- Pelvic instability is defined as inability of the pelvis to assume physiologic loads without displacement and functional compromise.
- Pelvic external fixation can serve several different purposes depending on hemodynamic and pelvic structural instability.
- Early external fixator application during resuscitative acute phase management can serve to control intrapelvic hemorrhage.
- External fixation of the pelvis may confer sufficient provisional stability to some injury patterns to facilitate patient mobilization. It may, however, prove inadequate in achieving long-term goals in the absence of additional surgical stabilizing efforts.
- With certain rotationally unstable yet vertically stable patterns, external fixation of the pelvis may serve as definitive management.

ANATOMY
- The pelvis provides structural continuity between the axial skeleton and lower extremities.
- The pelvis affords protection and passage for genitourinary, gastrointestinal, and neurovascular structures.
- Life-threatening massive hemorrhage, a complication of pelvic injury, can be of arterial (branches of the iliac system), venous plexus, or fracture surface origins.
- Additional concerns when treating pelvic ring trauma include injury to the lumbosacral and coccygeal nerves and male urethra.
- The anterior portion of the pelvic ring assumes minimal weight-bearing function and affords little pelvic ring stability.
- The pelvic ring is made up of the sacrum and paired innominate bones. Ligamentous, rather than osseous, support is the sole source of stability to the pelvis.
- Stability of the pelvis is particularly dependent on the tension band of the posterior weight-bearing sacroiliac complex (comprising the anterior sacroiliac ligaments, the interosseous ligaments, and the posterior sacroiliac ligaments) in addition to the iliosacral ligaments within the pelvic floor (sacrospinous and sacrotuberous). The iliolumbar ligaments confer additional stability between the axial skeleton (L5 transverse process) and the hemipelvis (ilium).

PATHOGENESIS
- Pelvic injury patterns (osseous or ligamentous) are determined by the direction, point of application, and magnitude of applied forces.
- Applied forces can be simplified into anteroposterior compression, lateral compression, and vertical shear. Actual forces and accordingly mechanism of injury are likely more complex.
- Resultant instability patterns are categorized as (1) vertically and rotationally stable, (2) rotationally unstable and vertically stable; and (3) rotationally and vertically unstable.
- Anteroposterior compression and hemipelvic rotational forces tend to result in injury to the “anterior ligamentous” complex (severity order: symphysis pubis, ischiosacral ligaments, anterior sacroiliac ligament). The integrity of the posterior tension band is preserved and vertical stability accordingly maintained (FIG 1A). Depending on the severity of injury to the anterior ligamentous complex, rotational instability may ensue.
- Lateral compression injuries, depending on severity, may result in internal collapse of the pelvis. Ligaments both anteriorly and posteriorly generally remain intact. Osseous injuries both anteriorly and posteriorly are typically stable impaction variants. Occasionally internal rotatory instability is sufficient to warrant surgical stabilization (external or internal fixation).
- Vertical instability implies disruption of the posterior tension band of the pelvic ring. This may be of osseous, ligamentous, or combined origin. Division of the sacrospinous and sacrotuberous ligaments in the presence of intact posterior ligaments will render a pelvis rotationally unstable. Further division of the posterior ligaments of the sacroiliac complex will result in both rotational and vertical instability. The involved hemipelvis is unstable in the axial, sagittal, and coronal planes (FIG 1B).
- Any injury mechanism (anteroposterior compression, lateral compression, vertical shear) may result in complete (vertical and rotational) instability if the magnitude of force is sufficient.

NATURAL HISTORY
- Life-threatening hemorrhage associated with pelvic fractures may be intrapelvic or extrapelvic. Identifying the source of bleeding may be challenging. In the absence of extrapelvic and intraperitoneal sources, external fixation of the pelvis may prevent life-threatening exsanguination.
- Early sheeting (circumferential external compression) may offer an initial beneficial hemodynamic response. Suspected sustained hemorrhage of indeterminate source may be intrapelvic arterial in origin. This may respond favorably to angiographic transcatheter embolization.
- Exploratory laparotomy, from the standpoints of role and timing, remains controversial.
- Imaging findings, results of diagnostic peritoneal lavage (if indicated), and response to fluid resuscitation must be considered before exposing the unstable trauma victim to the potential negative effects of abdominal exploration (decompression of intrapelvic tamponade, among others).
- Pelvic fractures associated with violation of the perineal, rectal, or vaginal regions must be identified immediately, and early measures directed toward preventing regional and systemic sepsis must be implemented. Appropriate soft tissue management requires early aggressive débridement and restoration of pelvic stability to facilitate wound care. External fixation is of paramount importance in many such cases, as is diverting colostomy.
Lumbosacral plexopathy may present in combination with sacral spinal canal or foraminal fractures. Pelvic reduction with restoration of stability and occasionally neurologic decompression may afford a more favorable prognosis if properly indicated and executed. Insufficient restoration of pelvic stability may result in complications associated with prolonged recumbency. Additional concerns include malunioin and nonunion. Lower extremity limb-length inequality and rotational deformity may result in functional deficits. Anterior ring injuries with significant displacement (tilt fragments) can result in sexual dysfunction, particularly in females.

PATIENT HISTORY AND PHYSICAL FINDINGS

The history, in terms of the mechanism of injury, offers insight into the energy of injury imparted. Force application and magnitude in turn determine pelvic injury and instability patterns as well as the type and frequency of associated injuries. The patient’s age may affect both physiologic reserve and bone quality. This dictates, respectively, the hemodynamic response and the energy of injury required to generate certain pelvic ring injuries. Preexisting medical comorbidities must be ascertained, as they may have considerable impact on survivability and complications associated with both operative and nonoperative management of pelvic injuries. Pelvic ring disruption is often accompanied by potentially life-threatening injuries to organs, vessels, and nerves within the pelvis, as well as other extrapelvic and closed cavity lesions of the abdomen, thorax, and head. Adequate adherence and response to principles of resuscitation must be assessed and primary and secondary surveys completed. Clinical evaluation includes inspection for abrasions, contusions, limb-length discrepancy, or abnormal rotation of the lower extremities. Palpation and manual testing for instability patterns may be pursued with caution. Stability is suggested (not confirmed) both radiographically and clinically. Identification of any open fracture variants and those with rectal or vaginal continuity is mandatory, as mortality rates in the presence of such lesions are considerable. Physical examination should include:

- Pelvic inspection to identify threatened or compromised soft tissues
- Inspection of lower extremities for limb-length inequality, rotational deformity, associated limb fractures or dislocations
  - Significant asymmetry in limb length or rotation implies rotational or vertical pelvic instability.
  - Further clinical examination or imaging of the limb is warranted if asymmetry is of other than pelvic origin.
- Assessment of pelvic instability
  - Lateral compression injury is implied by internal rotation and shortening.
  - Vertical shear injury is implied by external rotation and shortening.
- The genitourinary area is observed for regional hemorrhage. If present, it implies a urethral tear in a male and a vaginal tear in a female.
- Neurologic assessment to identify deficits in voluntary sphincter control or perianal sensation. Lumbosacral plexopathy implies pelvic instability.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Imaging studies offer a static view of the pelvis. These accordingly may imply but do not confirm stability (or instability) of the pelvis. Conventional radiography is initiated with performance of an anteroposterior (AP) radiograph of the pelvis. In the hemodynamically unstable patient, this image alone is sufficient to allow implementation of treatment. The pelvic inlet and outlet views in combination with the AP radiograph constitute the pelvic trauma radiographic triad (FIG 2A). The inlet view (FIG 2B) best depicts axial (most

### FIG 1 • A. An external rotation injury (AP compression) resulting in “anterior ligamentous complex injury.” Instability is rotational in character and demonstrated in the axial plane. The posterior tension band is intact and vertical stability is preserved. B. A vertical shear injury. In addition to compromise to the “anterior ligamentous complex,” the integrity of the posterior tension band is disrupted. The involved hemipelvis is unstable in all planes. (Modified from Buckle R, Browner B, Morandi M. Emergency reduction for pelvic ring disruptions and control of associated hemorrhage using the pelvic stabilizer. Tech Orthop 1995;9:258–266.)
often posterior) and rotational displacement. In contrast, the outlet view (FIG 2C) best demonstrates vertical displacement.

- Posterior pelvic displacement of more than 1 cm suggests posterior pelvic disruption. Symphyseal diastasis of more than 2.5 cm denotes disruption of the anterior ligament complex.
- Other radiographic clues implying vertical or rotational instability include the following:
  - Sacrospinous ligament avulsions (ischial spine or sacral border fractures)
  - Iliolumbar ligament avulsion (L5 transverse process fracture)
  - Sacral fractures or sacroiliac joint displacement
  - Stress radiographs (“push–pull” studies) may offer a dynamic interpretation of pelvic instability (FIG 3). Longitudinal load and traction are sequentially imparted to the lower extremity of the involved hemipelvis with manual stabilization of the contralateral extremity.
  - This is performed with the patient anesthetized and under AP radiographic control.
  - Such maneuvers are contraindicated in the presence of lumbosacral plexopathy, hemodynamic instability, or ipsilateral lower extremity fractures.
  - Computed tomography (CT) serves as a valuable adjunctive study. Cross-sectional axial images characterize posterior lesions best. Sacral foraminal and central spinal canal involvement is confirmed, as is integrity of the posterior tension band. Sacral impaction as opposed to gap displacement may suggest (but does not confirm) inherent stability.
  - The role of diagnostic and therapeutic angiography remains controversial with regard to management pathways.\(^4,9,16\) External fixation of the pelvis may effectively arrest venous and osseous hemorrhage (the source of 90% of intrapelvic hemorrhage). Sustained hemodynamic instability may suggest extrapelvic or intrapelvic arterial blood loss. In such cases exploratory angiography may be considered and therapeutic arterial angiographic embolization performed as necessary.
  - Diagnostic peritoneal tap and lavage (first described in 1965) has a poorly defined contemporary role.\(^{15}\) Procedure performance, indications, and assay result criteria (cell count) remain ambiguous. The presence of a pelvic fracture may contribute to a false-positive result.
  - Current imaging technology (contrast-enhanced CT, focused abdominal ultrasound) may prove a more reliable tool to determine the likelihood of abdominal injury and the need for laparotomy.

DIFFERENTIAL DIAGNOSIS

- Low-energy pelvic fractures in senescent bone
- High-energy pelvic fractures in younger patients with better-quality bone
Similar fracture patterns in the two groups above suggest a high magnitude of force in the younger population. This in turn is more commonly associated with additional injuries of concerning severity.
- “Non-ring” fractures: iliac crest, ischial tuberosity
- Ring fractures of increasing severity and instability
  - Rotationally and vertically stable
  - Rotationally unstable and vertically stable
  - Rotationally and vertically unstable

NONOPERATIVE MANAGEMENT
- Circumferential pelvic antishock sheeting may offer comfort and enhance ring stability. This noninvasive method employs readily available and inexpensive materials.
- Nonsurgical management is appropriate for lesions accurately deemed stable (confirmed on follow-up both clinically and radiographically).
- The goals for nonsurgical and surgical management are identical. These include avoidance or correction of deformity, maintenance of stability, and pain-free function.

SURGICAL MANAGEMENT
- The role of the external fixator must be defined before application. By decreasing pelvic volume, it offers intrapelvic tamponade. This, in addition to diminishing fracture motion, encourages hemostasis. In this capacity it serves as acute phase management.
- It may offer provisional stabilization of some injury patterns to facilitate patient mobilization. Attempts to stabilize vertically unstable lesions with external fixation alone are inadequate; these injuries require staged supplemental posterior fixation. Used for this purpose, it serves as provisional stabilization.
- Rotationally unstable yet vertically stable patterns may be amenable to external fixation as a source of definitive stabilization. Lesions with considerable symphyseal comminution unreceptive to anterior plating may be managed to union with external fixation, provided the posterior tension band remains functionally intact.

Preoperative Planning
- The surgeon must identify associated intrapelvic, vascular, urologic, and gynecologic comorbidities.
- The surgeon must confirm the patient’s neurologic status and document deficits. Soft tissues are inspected thoroughly and circumferentially.
- The surgeon characterizes, if applicable, the presence and type of pelvic instability, assigning the injury pattern to a classification scheme.
- The intended purpose of external fixator must be defined (resuscitation or provisional versus definitive stabilization).
If for purposes of provisional stabilization, the surgeon should determine the anticipated timing, sequence, and method of subsequent definitive stabilization.

- Frame design and pin location are selected (anterior iliac crest, supra-acetabular, posterior C-clamp) based on the pelvic injury pattern, the patient’s hemodynamic status, the available imaging, and surgeon familiarity.
- An immediate presurgical pelvic radiograph is obtained to assess the impact of retained bowel gas or contrast on imaging capability (if required).

### Positioning

- The patient is placed supine on a radiolucent table.
- Adequacy of imaging and efficacy of closed reduction maneuvers are confirmed.
- Preparation is done from the umbilicus to the anterior thighs, including both iliac crests.
- One or both lower extremities are included circumferentially as required to effect rehearsed closed reduction maneuvers.

### Approach

- Adequate fixation and accordingly proper pin placement are the principal requirements for restoring pelvic stability when applying an external fixator.
- Pins for purposes of anterior pelvic external fixation may be placed either in the anterior iliac crest or in the supra-acetabular region (FIG 5).
- Ease of insertion is an important attribute when applying a resuscitation frame.
- Pin placement within the iliac crest is more expeditiously performed and lacks significant regional anatomic hazards.
- On occasion, this area may be compromised by soft tissue concerns or proximity to fracture planes.
- In such cases, pin placement within the supra-acetabular region is an option.

- Pins and frames in this lower position may offer improved access to the abdomen and unlike pins placed within the iliac crest are less irritating to anterolateral abdominal soft tissues.¹⁸
- In an obese patient, these pins (supra-acetabular) may be better tolerated and less prone to loosening and infection.
- The dense bone of the supra-acetabular region offers stability of fixation as good as or better than the iliac crest.
- Some authors investigating the biomechanical performance of these pins (supra-acetabular) demonstrated superior purchase within bone and diminished displacement of posterior portions of the pelvic ring.¹¹
- Because supra-acetabular pin insertion is more time-consuming and instrumentation and fluoroscopy dependent, its role as a resuscitative measure is limited.
- The pelvic antishock clamp (C-clamp) is a posteriorly (or trochanteric) applied device that may offer greater stability to vertically unstable fractures than anteriorly applied frames (FIG 6).¹,¹⁰ It is designed for the emergent treatment of unstable pelvic ring injuries.

  - The device is indicated in both rotationally and vertically unstable pelvic ring injuries.
  - It is contraindicated in lateral compression injuries and fractures involving comminution of the iliac wing or sacrum. If the device is used in lateral compression-type injuries, it may accentuate the deformity. Use of the pelvic antishock clamp with iliac wing fractures may lead to the pins traversing the fracture sites, subsequently causing internal injury.

---

**FIG 5** • The anterior hemipelvis offers two sites for pin insertion: the iliac crest (superiorly) and the supra-acetabular region (more inferiorly). **A.** Profile view. **B.** Frontal view.

CIRCUMFERENTIAL PELVIC ANTISHOCK SHEETING

- Several techniques of noninvasive external pelvic ring stabilization have been described. Among them are the use of inflatable antishock trousers and spica casts. These do not permit abdominal access, they require skill and familiarity, and they conceal the abdomen.

- The simple application of a circumferential bed sheet may be considered during the resuscitation of the hemodynamically unstable patient. Unlike methods described above, this technique requires materials that are inexpensive, easy to apply, and readily available. No incisions that may jeopardize subsequent operative procedures are required. The sheet may be positioned to allow assessment of abdominal and lower extremity regions.

- The patient’s clothing should be removed before application. The sheet ends are crossed and overlapped anteriorly.

- The position of sheet application is directed more at the level of the greater trochanters of the hips than more proximally at the injured pelvis. Clamps secure the snugged sheets (TECH FIG 1).

- Long-term pelvic sheeting is discouraged as soft tissue compromise is a concern. It is contraindicated in the presence of unstable lateral compression injuries. Its use in such situations may aggravate deformity, resulting in internal visceral injury and posterior neurologic compression.

- Pelvic circumferential compression devices may offer the simplicity and effectiveness of sheeting with the benefit of feedback controlled force. This may prevent inadequate or excessive compression.

ANTERIOR ILIAC CRESCENT: OPEN TECHNIQUE

- A manual trial reduction is recommended before establishing a site for a skin incision.

- An 8- to 10-cm oblique wound adjacent and parallel to the iliac crest anteriorly is established.

- This incision is made in the anticipated site of the reduced hemipelvis to minimize tension on soft tissues (TECH FIG 2A).

- Dissection continues through skin and subjacent soft tissues, allowing palpation of the underlying iliac crest.

- Subperiosteal elevation of the external oblique exposes the inner table (TECH FIG 2B,C).

- Subperiosteal elevation of the hip abductors exposes the outer table (TECH FIG 2D).

- Exposure of the inner and outer tables continues within the confines of the surgical wound.

- The thick anterior pillar is identified (TECH FIG 2E).

- The surgeon’s index digit is introduced, confirming inner table inclination.

- The surgeon’s thumb and index fingers palpate the outer and inner tables respectively to aid in establishing proper pin orientation within the two tables (TECH FIG 2F).

- The first pin is placed anteriorly within the anterior pillar, about 1 to 2 cm posterior to the anterior superior iliac spine.

- The iliac crest anteriorly is asymmetric with regard to cross-sectional anatomy.

- The ideal starting point is thus along the medial third of the crest at the junction of the inner and middle thirds (“rule of thirds”) (TECH FIG 2G).

- Pins placed centrally or laterally are likely to be misdirected, exiting the desired intercortical path (TECH FIG 2H).

- A unicortical drill hole, no more than 1 to 2 cm deep, initiates access within the crest.

- Pin direction is judged by manually grasping the crest within the surgeon’s digits as described. This is typically 25 to 45 degrees medially and 10 to 15 degrees caudad.
The pin may be introduced through the established surgical wound or adjacent (medial) percutaneous ones (TECH FIG 2J).

- The pin is advanced 5 cm (50-mm threaded 5.0-mm-diameter pin), directed within the pillar between the osseous tables of the ileum.
- The second pin and the third if applicable are inserted one fingerbreadth posterior to the previous pin.
- The narrow and curved profile of the crest does not allow parallel pin insertion and on occasion accommodates no more than two pins.
- Subsequent pins should appear to converge toward each other and the common target of the supra-acetabular region within the anterior pillar (TECH FIG 2J).

- In an effort to retain intrapelvic tamponade, pins may be introduced through a similar approach without elevation of periosseous muscular attachments.
- Small Kirschner wires or spinal needles are directed along the iliac fossa to orient proper pin placement.
- Inner and outer table soft tissue attachments are preserved. Hematoma is not accessed and intrapelvic tamponade is preserved.
- A fluoroscopic obturator oblique outlet view of the pelvis can aid in identification of misdirected pins exiting the desired intercortical path (TECH FIG 2K).

**TECHNIQUES**

**TECH FIG 2 • Anterior iliac crest pin insertion, open technique.**

A. The skin incision is made at the anticipated site of the reduced iliac crest. B,C. The internal oblique is elevated from the inner table. D. The hip abductors are elevated from the outer pelvic table. E. The thick osseous pillar (*) is the desired site of pin insertion. (continued)
F. Palpation of the inner and outer tables confirms proper pin trajectory. G. The “rule of thirds” (cross-sectional junction of inner third and outer two thirds of the crest) aids in establishing the preferential pin entry point. H. This facilitates pin insertion, preventing misdirection and premature exit. I. Alternatively, pins may be placed through percutaneous wounds subjacent to the open surgical incision. J. Pins should converge on the supra-acetabular region while remaining within the anterior pillar. K. Fluoroscopic guidance facilitates proper pin placement within the inner and outer tables. (A: Modified from Yang AP, Iannacone WM. External fixation for pelvic ring disruptions. Orthop Clin North Am 1997;28:331–344. J: Modified from Poka A, Libby EP. Indications and techniques for external fixation of the pelvis. Clin Orthop Relat Res 1996;329:54–59.)
ANTERIOR ILIAC CREST: PERCUTANEOUS TECHNIQUE

- Stab wounds 1 to 2 cm long are directed perpendicular from the anterior iliac crest toward the umbilicus (TECH FIG 3).
- This orientation diminishes undesirable soft tissue tension around the pin on pelvic reduction and greatly enables pin tract release in the event of impending pin tract infection.
- After completing the skin incision, dissection continues by spreading a surgical clamp, clearing away subcutaneous fat.
- Through these small wounds, Kirschner wires or spinal needles can be introduced along both sides of the iliac wing.
- This provides a targeting method to accurately position the pins within the two tables of the ilium.
- Guided by the spinal needles, a soft tissue trocar assembly is introduced and situated medial of the midline to account for lateral overhang ("rule of thirds").
- Sagittal plane orientation of the pin must be considered as well.
- This requires that the drill be held more cephalad (directed caudad) than expected to allow proper position within the desired supra-acetabular bone (superior and cephalad to the acetabulum), rather than the thin bone of the ilium. Triple cannulated drill sleeves are used to protect soft tissues.
- The fixation pin is inserted, allowing the cortical walls of the ilium to establish direction. An image intensifier may aid in elective nonemergent fixator application.

SUPRA-ACETABULAR TECHNIQUE

- The patient is positioned supine on a radiolucent table.
- Safe introduction and proper positioning of the pin require the assistance of fluoroscopic guidance.
- The open approach for pin placement begins with a vertically oriented 5- to 10-cm incision, depending on patient body habitus and prereduction pelvic deformity. A smaller transverse incision has been described in addition to entirely percutaneous techniques of pin insertion.
- This vertical approach begins along the lateral border of the anterior superior iliac spine, extending distally and lateral to the anterior inferior iliac spine.
- The interval between the sartorius and tensor fascia lata is identified (TECH FIG 4A).
- Tissue planes are developed with blunt dissection and the anterior inferior spine is palpated.
- The lateral femoral cutaneous nerve is most commonly identified medial to the anterior iliac spine.
- Anatomic studies have demonstrated the lateral femoral cutaneous nerve to have a variable course, often within 10 mm of inserted pins.\(^6\)
- With blunt dissection and the use of protective drill sleeves, the lateral femoral cutaneous nerve may be adequately protected.
- Supra-acetabular pins should be inserted no less than 2 cm proximal to the joint to avoid intra-articular penetration. Capsular extension of the hip may be up to 16 mm superiorly.
- An obturator oblique view with slight cephalad angulation (obturator outlet view) is first obtained. A metallic marker is positioned 2 cm proximal to the hip joint under fluoroscopic control (TECH FIG 4B).
- The trocar assembly is positioned under fluoroscopic control superior to the hip joint.
- Only the outer cortex is drilled. A triple cannulated guide facilitates atraumatic drill and pin insertion.
- The drill, followed by the pin, is directed within the pelvis, avoiding intra-articular penetration of the hip joint.
- Pin angulation is typically 20 degrees medial from the vertical axis and slightly cephalad.
- The drill is directed toward and superior to the sciatic notch (30 to 45 degrees in the sagittal plane). Fluoroscopic guidance (iliac oblique view with slight cephalad angulation) ensures proper pin trajectory and depth of insertion (TECH FIG 4C,D).
- Intercortical pin orientation within the tables of the pelvis is monitored on an obturator oblique inlet view ("rollover view") (TECH FIG 4E,F).
- A 5-mm-diameter 50-mm thread length pin is inserted to the depth of the threads.
- A second pin may be inserted proximal to the first, if desired.
No frame, regardless of complexity, restores sufficient definitive fixation to vertically unstable lesions. Accordingly, simple constructs are preferred to permit patient mobilization, abdominal access, and performance of subsequent diagnostic and therapeutic procedures. Accurate pin placement within the curved iliac crest mandates a nonparallel converging pin pattern. Pin clamps with a straight configuration require that pins be prestressed to conform and accommodate such clamps (TECH FIG 5A). Those with an independent ball joint design offer an attractive alternative (TECH FIG 5B).

Applied pin clamps should remain three fingerbreadths above the skin surface. This is less threatening to subjacent soft tissues and permits adequate pin tract care. The frame is fabricated with inclusion of universal ball joints and reduction is performed. Anteroposterior compression injuries are reduced with midline-directed compression and lateral compression injuries with distraction. Adjunctive lower extremity skeletal traction may be considered for vertically displaced patterns. Bar-to-bar connectors are next secured and operative incisions are closed and dressed.
TECH FIG 5 • Pin clamps: straight (A) and multiplanar (B).

PELVIC ANTISHOCK CLAMP: C-CLAMP

- The surgeon can choose between two coronally oriented pin placement positions (anterior or posterior) (TECH FIG 6A). Anterior pins are placed in the dense column of bone of the gluteal ridge. Anterior pin placement will allow for compression of the anterior and, to some degree, the posterior pelvic ring. Posterior pin placement allows for compression of the posterior pelvic ring.
- Landmarks for anterior pin placement include the anterior superior iliac spine, the tip of the greater trochanter, and the axis of the femur.
- The surgeon should ensure that the patient’s legs are not externally rotated, as this will place pins too far posterior.
- The surgeon finds the gluteal ridge, which is three fingerbreadths posterior to the anterior superior iliac spine on the iliac wing.
- Next, the surgeon locates the tip of the greater trochanter and the axis of the femur with legs in neutral rotation.
- The center of the line connecting the gluteal ridge and the greater trochanter corresponds to the pin site.

TECH FIG 6 • Pelvic antishock clamp. A. Anterior and posterior sites of application. B. Pin site. (continued)

- Landmarks for posterior pin placement include the anterior superior iliac spine, posterior superior iliac spine, and dorsal axis of the femur. A line is drawn between the anterior and posterior superior iliac spines. The intersection of this line and the dorsal axis of the femur corresponds to the pin site. The pin site should be about 4 to 5 cm anterior to the posterior iliac spine (TECH FIG 6F). The surgeon must avoid the greater sciatic notch and the soft bone of the iliac fossa.

- The pin site is infiltrated with local anesthetic and an incision is made. Blunt dissection is carried down to bone. The pins are adjusted to be in a single axis. This orientation allows rotation of the C-clamp, permitting abdominal access. Reduction of any vertical displacement is now completed with traction.

- Alternatively, the C-clamp may be directly applied to the trochanteric region of the femur. The anatomic hazards of the previous method of application are thus avoided. In this manner, it serves a role similar to circumferential sheeting.
PEARLS AND PITFALLS

Enhancing pin fixation
- The pin–bone interface has maximal stress concentration and represents the weakest component of the external frame assembly.
- Bone quality, frame rigidity, pin number, and pin placement and diameter can all affect the strength of the pin–bone interface.
- The insertion length, also referred to as the intercortical distance, greatly influences pullout forces.
- As a general rule, pins should be maintained within the two cortices as long as possible. Distal cortical penetration is technically undesirable and should be avoided.
- Pins of adequate intercortical distance consistently appear to outperform those with transcortical purchase (undesired extracortical exit).

Avoiding conflicting surgical exposures
- Surgical wounds and pin location in the supra-acetabular region are less likely to compromise future anticipated surgical wounds. This is particularly important if anterior access to the sacroiliac joint is anticipated and pursued later.

Anterior iliac crest wound
- The surgical wound anteriorly should be placed in the anticipated region of the hemipelvis after reduction. This minimizes tension on soft tissues.
- Percutaneous wounds may be made adjacent to the open exposure to allow pin introduction.
- The wound is closed before frame application.

Anticipating pin trajectory in the unreduced pelvis
- Pin inclination in the unreduced pelvis does not reflect normal parameters.
- Depending on deformity, pin inclination may be more vertical (lateral compression) or horizontal (externally rotated, AP compression).

Avoiding extrapelvic misguided pins
- “Preferential errors” do exist!
- For AP compression injuries, an internal exit is preferred. For lateral compression injuries, an external exit is preferred. This maintains three-point fixation in a mechanically advantageous manner.

Overcompression is possible
- Depending on the method of application, reduction, and fracture pattern, compression with an anteriorly applied frame may accentuate posterior displacement.

POSTOPERATIVE CARE
- After satisfactory application of the frame, individual pin sites are scrutinized and soft tissues are released to prevent tension-induced necrosis and subsequent infection.
- Post-application imaging confirms pelvic stability, symmetry, and indications for additional anterior or posterior (open or percutaneous) stabilization techniques.
- Pin sites are debrided of organized blood and cleansed once or twice daily with peroxide solution. Dressings may be applied (if inspected regularly) or the wounds may be left open. Peripheral pin site tension should be released with sharp dissection under local anesthesia. Regional necrosis and subsequent pin tract sepsis are thereby avoided.
- Mobilization and weight bearing are dictated by the injury pattern and designated stability classification.

OUTCOMES
- Severe hemodynamic instability on arrival is a useful predictor of mortality and transfusion demands. Death within the first 24 hours is often due to acute blood loss; after this time it is usually secondary to multisystem organ failure.
- Reported mortality rates of open pelvic fractures range from 10% to 45%. These injuries are often associated with injuries of prognostic significance. Life-saving strategies to address this problem continue to evolve. The degree of pelvic instability clearly parallels rates of morbidity and mortality.
- Vertically unstable fractures, despite adequate contemporary management, have significant neurologic and associated injuries that remain of long-term consequence and disability. Those with rotational instability alone have a considerably more favorable prognosis.17,26
- The transient use of external fixation is efficacious if its role and indication are clearly defined. Use for definitive treatment is associated with a high rate of infection and aseptic pin loosening. Unstable posterior lesions are adequately managed with external fixation alone.

COMPLICATIONS
- Sheeting: overcompression (lateral compression injuries)
- General: pin tract sepsis, loss of pin fixation, malreduction, loss of reduction14
- Anterior external pelvic fixation: inadequate or aggravated posterior alignment
- Supra-acetabular pin placement: lateral femoral cutaneous nerve injury, intra-articular hip penetration, sciatic notch neurovascular injury
- C-clamp: intrapelvic pin penetration

REFERENCES
DEFINITION
- The pubic symphysis comprises a fibrocartilaginous disc between the bodies of the two pubic bones.
- A diastasis of the pubic symphysis indicates a disruption of the pelvic ring and an unstable pelvis.
- The symphysis is disrupted in anterior–posterior compression (APC) injuries as classified by Young and Burgess and occasionally in lateral compression fractures.

ANATOMY
- The symphysis is an amphiarthrodial joint, consisting of a fibrocartilaginous disc, and stabilized by the superior and inferior arcuate ligaments (FIG 1A).
- The corona mortis is a vessel that represents the anastomosis between the obturator artery and the external iliac artery. It is located about 6 cm laterally on either side of the symphysis (FIG 1B).14
- Lateral to the symphysis on the superior rami is the pubic tubercle, a prominence representing the attachment of the inguinal ligament.
  - This bony landmark must be accounted for when contouring a plate that is going to span the symphysis.
  - Anatomic variation exists between the sexes, with females having a wider and more rounded pelvis, making their anterior pelvic ring more concave than males (FIG 2).
  - The pelvic arch formed by the convergence of the inferior rami tends to be more rounded in females because their pubic bodies are shallower than males.
  - The arcuate ligaments are the main soft tissue stabilizers of the anterior pelvis.
  - These ligaments are both superiorly and inferiorly and are firmly attached to the pubic rami.
  - The sacrospinous and sacrotuberous ligaments play an important role in the stability of pelvic fractures. These ligaments connect the sacrum to the ilium via the ischial spine and the ischial tuberosity. The sacrospinous ligament resists the rotational forces of the hemipelvis, and the sacrotuberous ligament prevents rotation as well as translation of the hemipelvis.13
  - If these ligaments and the pelvic floor are torn in conjunction with a pelvic fracture, symphyseal widening is more significant (see Chap. TR-1).4

PATHOGENESIS
- The Young and Burgess classification describes the injury by the type of force acting on the pelvis. Symphyseal diastasis is most commonly seen in APC injuries or open book pelvis injuries.
- In APC injuries minor widening of the symphysis may not involve disruption of the pelvic floor, including the sacrospinous ligaments.
- In cadaver pelvis, where the symphysis and sacrospinous ligaments were sectioned, more than 2.5 cm of symphyseal widening was observed, thus defining a rotationally unstable pelvis.12
- If the pelvic floor and the sacrospinous ligaments are torn, the involved hemipelvis can externally rotate down and out,
rotating on the intact posterior sacroiliac ligaments and creating an unstable pelvis (FIG 3). \(^4\)
- Occasionally, lateral compression (LC) injuries involve fractures of the pubic rami and a symphyseal disruption. This occurs when the compressed hemipelvis causes the contralateral rami to fracture and the contralateral symphyseal body to tilt inferiorly. Because one side of the symphysis is off and can compress the bladder or uterus, altering the pelvic ring, it should be reduced to the other pubic body, which remains intact.
- These are referred to as tilt fractures, and open reduction and internal fixation should be considered to prevent impingement of the birth canal and bladder. \(^13\)
- A diastasis of the pubic symphysis can also occur in pregnancy and during childbirth because of hormonally induced ligamentous laxity. This can lead to chronic instability, and stabilization of the symphysis has been shown to relieve painful symptoms. \(^16\)

**NATURAL HISTORY**
- Persistent low back pain, anterior pain, sitting imbalance, and an impaired, painful gait are common sequelae after pelvic fractures.
- Early studies looking at pelvic fractures without surgical treatment demonstrated that almost a third of these patients had disabling pain and impaired gait. Only a third had no symptoms if the posterior ring was involved. \(^16\)
- APC type I injuries are Tile type A stable pelvic injuries, which do well with nonoperative treatment. These injuries tend to occur in younger patients involved in motor vehicle trauma or in elderly patients as a result of a direct injury such as a fall.
- APC type II and III injuries are unstable injuries. Nonoperative treatment has resulted in late pain in these injuries. In a retrospective study by Tile, APC type II injuries treated nonoperatively had a 13% incidence of late pain, with the majority of patients reporting persistent moderate pain. The patients with APC type III injuries reported a 16% incidence of late pain, with most pain being reported as moderate or severe. \(^13\)
- Patients with pelvic trauma tend to have other organ systems involved, and these associated injuries contribute to long-term disability. The more severe injuries associated with pelvic fractures are urologic and neurologic injuries. \(^16\)
- Whitbeck et al demonstrated higher morbidity and mortality rates as well as an increased incidence of arterial injuries in APC type III injuries compared to other pelvic fractures. \(^18\)
Disruption of the pubic symphysis is associated with urologic injuries. Bladder ruptures and urethral tears occur about 15% of the time in association with pelvic trauma and can lead to late complications such as strictures and incontinence. These associated injuries potentially lead to a higher infection rate when open reduction and internal fixation is performed. An increased incidence of incontinence has also been seen in women with APC injuries.

Neurologic injuries associated with pelvic fractures occur when there is posterior pathology and are more common with sacral fractures and vertically unstable fracture patterns.

Dyspareunia and sexual dysfunction are also described as complications after pelvic fractures. They can occur directly from the injury or as a result of ectopic bone formation during healing.

Symphyseal pelvic dysfunction, a relatively common condition, presents as anterior pelvic pain secondary to the laxity in the symphysis. This condition typically resolves spontaneously and can take some time but needs to be differentiated from traumatic symphyseal diastasis as a result of childbirth. Traumatic diastasis occurs in about 1 in 2000 births to 1 in 30,000 births, and the diastases from pregnancy can be as great as 12 cm.

Most patients with postpartum displacement recover with no residual pain or instability after treatment with pelvic binders, girdles, and the recommendation to lie in the lateral decubitus position.

There are a limited number of studies looking at symphyseal disruption secondary to pregnancy. The exact incidence of persistent long-term pain is unknown, but chronic pelvic instability can occur if it is unrecognized.

In the few series reporting operative treatment, the indication was persistent pain for at least 4 to 6 months postpartum.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Pelvic injuries usually occur as a result of any high-energy trauma, such as high-speed motor vehicle accidents, motorcycle accidents, or falls from heights.

Patients with pelvic fractures may become hemodynamically unstable, and close monitoring of blood pressure and fluid requirements is needed.

Typically, if a patient requires more than 4 units of blood to maintain hemodynamic stability, an angiogram should be obtained to diagnose and embolize any arterial injuries. Clotting factors and platelets should also be administered.

Patients may have tenderness to palpation in the area of the symphysis. If motion of the pelvis is detected, manipulation of the pelvis should cease, as unnecessary manipulation may disturb any clot formation (see Exam Table for Pelvis and Lower Extremity Trauma, pages 1 and 2).

If there is no radiographic demonstration of displacement, the iliac wings can be compressed to test for stability of the pelvic ring and each hemipelvis.

A careful examination of the skin to identify areas of ecchymosis and hematoma formation, particularly in the flanks, groin, and abdominal regions, also needs to be performed.

The presence of a Morel-Lavalle lesion indicates that high-energy trauma has occurred in the pelvic region (FIG 4). Recognition of this lesion is important to prevent infection.

A good pelvic examination and evaluation of the perineum are essential. Swelling or open wounds in the perineal area may indicate a high-energy mechanism of injury. Open injuries require emergent management.

Evaluation of other organ systems, looking for associated injuries, is essential.

In males, a high-riding prostate on the rectal examination or blood at the meatus may indicate injury to the urethra or bladder, and placement of a Foley catheter should be delayed until a retrograde urethrogram is performed, unless the patient is in extremis.

Urethral injuries are less common in females because the urethra is shorter.

A thorough neurologic examination of the lower extremities also needs to be performed, as injuries to the L4 and L5 nerve roots can occur in pelvic fractures. It is essential to test the sensation and motor functions of specific roots, identifying any neurologic injury that can differentiate between a nerve root lesion or a more central lesion.

A limb-length discrepancy or a rotational deformity of the lower extremities should prompt radiographic evaluation of the pelvis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Radiographic evaluation of the pelvis consists of anteroposterior (AP), inlet, outlet, and Judet views (FIG 5).

A retrograde urethrogram and sometimes a CT cystogram should be performed to rule out an injury to the genitourinary system in men. A CT cystogram is sufficient for females.

A CT scan of the pelvis is also indicated to help evaluate intra-articular injuries to the sacroiliac joints and further delineate the fracture pattern.

A CT angiogram can also be used at the time of the trauma scan to help predict if an arterial bleed is present and requires further treatment with angiography and embolization.

Angiography may be used to treat patients who are hemodynamically unstable and do not respond to standard resuscitation, particularly if a CT angiogram indicates arterial bleeding.

A stress examination in the operating room can be performed under fluoroscopy to assess stability if there is a question of an unstable pelvis.

Single-leg stance views can also be performed if it is not clear whether an injury is unstable. This is a good examination for evaluating patients who may have chronic instability, such as a female patient with ligamentous laxity secondary to pregnancy or unrecognized pelvic injury.

**DIFFERENTIAL DIAGNOSIS**

- Rami fractures
- Symphyseal strain
- Hip fracture

![FIG 4 • Morel-Lavalle lesion.](image-url)
Muscle strain or avulsion
- Lumbar fracture

**ACUTE MANAGEMENT**
- The patients should be hemodynamically stabilized.
- The pelvis can be stabilized by placing ankles together with Ace wraps. Heels and ankles should be padded to prevent skin breakdown and ulcer formation.
- Placing a sheet across the pelvis at the level of the greater trochanters can be used to reduce the symphysis and temporarily stabilize the pelvis. The sheet can be affixed with towel clips to hold it with tension rather than tying a knot across the abdomen (see Chap. TR-1).

**NONOPERATIVE MANAGEMENT**
- If minimal separation of the symphysis is present, the patient can be made non-weight bearing on the affected side and can be allowed to ambulate.
- Close radiographic monitoring should ensue, with weekly radiographs. Single-leg stance views can be used to help identify late instability.

**SURGICAL MANAGEMENT**
- A diastasis larger than 2.5 mm indicates a disruption of the sacrospinous ligaments and thus an unstable pelvis. Open fixation of the symphysis stabilizes the anterior pelvis.\(^2\)
- Open injuries can be stabilized with external fixation, using iliac wing pins or Hanover pins placed at the level of the anterior inferior iliac spine. Refer to Chapter TR-1 for more details.
- In APC type II injuries with an intact hemipelvis, no posterior fixation is needed, and the symphysis is reduced and stabilized first.
- For type III injuries, if the innominate bone is broken, the anterior pelvic ring is reduced and fixed after the posterior ring is reduced and fixed. The anterior pelvic ring is reduced and fixed as a first step if the innominate bone remains intact.
- Indications for anterior stabilization for vertically unstable pelvic fractures include improving anterior stability to the pelvic ring, stabilizing a pelvic injury that is associated with an injury requiring a laparotomy, treatment of bone protruding into the perineum (ie, a tilt fracture), or in association with an acetabular fracture requiring open reduction.\(^3\)

**Preoperative Planning**
- The surgeon should review appropriate radiographic studies (AP, inlet, and outlet views and CT scan).
- Identifying all rami fractures and the presence of any pubic body fractures is essential, as this will help determine how to obtain a reduction as well as dictate the type of fixation necessary.
- The surgeon should plan to obtain stress views in the operating room to determine the stability of the pelvis if there is any question of stability.
- The surgeon should rule out the presence of a bladder rupture or urethral tear. If one is present, repair should be performed at the same time as internal fixation of the symphysis if possible to avoid a more complex late reconstruction.
- Any history of previous abdominal surgery or the presence of prior incisions should be identified before going to the operating room.
- The proper equipment must be available, such as C-arm, radiolucent table, large bone clamps, external fixation equipment, and a C-clamp.

**Positioning**
- The patient is placed on a radiolucent flat-top table with legs together to facilitate reduction of the symphysis.
- Fluoroscopic radiographs confirming the ability to obtain a good inlet and outlet views with the C-arm are obtained before preparing and draping the patient.
Right-handed surgeons may prefer to have the C-arm on the patient’s right side and the drill and instruments on the patient’s left for easier access to the symphysis with the drill. Placement of a Foley catheter is needed to decompress the bladder; it can also be felt intraoperatively to help identify the bladder. Venodyne boots are placed on both legs if possible for deep vein thrombosis prophylaxis during the case.

Approach

Open reduction of the symphysis is performed with an anterior Pfannenstiel approach.

**PFANNENSTIEL APPROACH**

- The entire lower abdomen is prepared, including both anterior superior iliac spines, the symphysis, and the umbilicus.
- Access to the anterior superior iliac spines is important if an external fixator is to be placed to assist in reduction or for additional fixation.
- A transverse incision is made 2 cm above the symphysis (TECH FIG 1A).
- Once through the skin, a large rake is placed to help create a plane above the rectus fascia.
- A longitudinal incision is then made along the fascia of the linea alba. The rectus muscle insertion is not taken down, although it is common to see an avulsion of one of the rectus muscles off the rami from the initial injury (TECH FIG 1B).
- Blunt dissection is continued longitudinally to spread the rectus muscle and protect the underlying peritoneum and bladder.
- Electric cautery can be used to divide the remaining fibers of the rectus while protecting the underlying structures.
- The bladder and bladder neck are evaluated for the presence of any injury.
- At this point, a blunt malleable retractor can be placed into the space of Retzius to protect the bladder (TECH FIG 1C).
- Care should be taken laterally, as the vessels known as the corona mortis tend to be about 6 cm lateral to the symphysis.
- The corona mortis is an anastomosis of the obturator and external iliac arteries (see Fig 1B).¹⁴
- Hohmann retractors are placed through the periosteum superiorly over the superior pubic rami one side at a time to retract the rectus muscle laterally and expose the superior body of the symphysis.
- These retractors are placed close to the external iliac vessels, so they need to be placed with care directly onto bone.
- The periosteum on the superior aspect of the rami can now be stripped off with an electric cautery and osteotomes.
- Some surgeons remove the symphyseal cartilage to promote fusion, and we agree with this approach.

**WEBER CLAMP REDUCTION**

- Once the superior aspect of the symphyseal bodies is exposed, the Weber clamp is placed anteriorly to avoid removing the insertion of the rectus (TECH FIG 2A).
- The goal in using this technique is to have the tips of the Weber clamp at the same level on each symphyseal body.
- If anterior displacement is present on either side, the tip of the clamp is placed slightly anterior on that side so at the time of reduction the tips are at the same level.⁴
- The clamp is tilted distally to engage the tines (TECH FIG 2B).
- The clamp is placed anterior to the rectus insertions.
USE OF A C-CLAMP TO AID IN REDUCTION

- The C-clamp has been described for use in unstable APC pelvic fractures in patients requiring an exploratory laparotomy or as temporary pelvic fixation if the patient cannot go to the operating room. It can also be used to assist in the open reduction of the symphysis if conventional clamps cannot hold the reduction.
- This is a similar concept to the one described by Wright et al for assisting in the reduction of the posterior pelvic ring.17
- To apply the C-clamp, the pins are placed two fingerbreadths directly posterior to the anterior superior iliac spine. This places the pins in the gluteus pillar, a thickened portion of the lateral ilium above the acetabulum (TECH FIG 3A).

Once the pins are in place, the clamp can be fitted onto the pins. The clamp is then used to compress the pelvis and reduce the rotationally unstable hemipelvis (TECH FIG 3B,C). Once reduced, the clamp is tightened and locked down. Fluoroscopy is used to confirm reduction of the symphysis as well as any posterior pathology. (See Chap. TR-1 for further description of the C-clamp.)
- Care should be taken not to overreduce rami fractures if they are present.
- The goal of this technique is to obtain most of the reduction and then fine-tune the reduction once the symphysis is exposed in the usual manner with the Weber clamp.
JUNGABLUTH CLAMP REDUCTION (TECHNIQUE OF MATTA)

- Jungabluth clamp reduction is used when the innominate bone is intact and the posterior ring is unstable.
- The innominate bone tends to be externally rotated, posteriorly displaced, and superiorly translated. If this is the case or vertical instability exists, the entire innominate bone needs to be manipulated to obtain a reduction.
- In these cases, the use of the Jungabluth clamp may be necessary to achieve reduction.
- Drill holes are made in an anterior-to-posterior direction for the placement for 4.5-mm screws.
- For the screw being placed on the unstable side (with posterior displacement), a 4.5-mm gliding hole is drilled and the screw is secured to the bone through a small plate on the posterior side of the pubis using a nut (TECH FIG 4A,B).
- The plate will act as a washer and provides a larger surface area of force to be exerted on the hemipelvis so one does not have to rely on the pullout strength of a single screw.
- The Jungabluth clamp is then placed anteriorly and secured to the 4.5-mm screws and can then be used to achieve the reduction (TECH FIG 4C,D).5

TECH FIG 4 • The Jungabluth clamp can be used to reduce the symphysis if there is posterior translation of the hemipelvis and intact innominate bone. A,B. On the side of the displacement, a screw is placed with a small plate attached with a nut so the plate acts a washer. C,D. The clamp is then attached to the head of the screw and is used to pull the hemipelvis forward to reduce the symphysis. A gliding hole must be used so the clamp pulls through the plate and does not rely on the pullout strength of a single screw. (Adapted from Matta JM, Tornetta P. Internal fixation of pelvic fractures. Clin Orthop Relat Res 1996;329:129–140.)
PLATE PLACEMENT

- Before fixation placement, the reduction should be confirmed on the AP, inlet, and outlet views with the C-arm.
- With the symphysis reduced, a six-hole, curved 3.5 reconstruction plate or precontoured plate is placed across the symphysis.
- A Kirschner wire can be placed into the fibrocartilaginous disc space to aid in centering the plate.
- Before the plate is placed, it is contoured to fit the curve of the superior surface of the symphysis and rami. The ends are contoured if a six-hole plate is used to allow for anatomic contact to the ramus (TECH FIG 5A). Alternatively, precontoured plates can be used.
- In a six-hole plate, the two medial screws on each side go into the symphyseal body and the most lateral screw goes into the rami.
- Careful planning of screw placement must be considered if the Jungabluth clamp is used so that the screws are placed into the plate without loosing the reduction.
- The first screws placed are adjacent to the symphysis on either side (TECH FIG 5B).
- The drill hole should be placed eccentrically, laterally in the hole to generate compression. The drill should be oriented parallel to the posterior aspect of the symphyseal body.
- The proper angle can be determined by using a finger to feel the inner surface of the pubic body, using it as a guide for the drill (TECH FIG 5C).
- These initial screws should be angled slightly anteriorly and laterally in the pubic body so that they stay in bone and achieve the best bite.
- These screws can be placed to go down to the ischium if necessary.

**TECH FIG 5** • **A.** Example of how the plate needs to be contoured to accommodate the pubic tubercle on either side of the symphysis. The concavity of the plate also has to be contoured, and this can vary between genders (see Fig 2).  **B.** Clinical photograph of plate after all screws are placed. Numbering indicates the order of screw placement, with the screws closest to the symphysis being placed first. After screws 1 and 2 are placed, any order may follow for the remaining screws.  **C.** Drilling the proper angle is imperative to ensure the screw will stay in bone. To gauge the angle, one may place a finger on the posterior aspect of the pubic body and then drill parallel to that finger to ensure the drill is held at the proper angle.  **D–F.** Postoperative AP, inlet, and outlet view radiographs of a pre-contoured plate and a reduced symphysis.
The two most medial screws on each side of the symphysis can be placed either parallel to each other or in a crossing pattern within the symphyseal body (TECH FIG 5D–F).

The lateral screws in the plate are placed last and will be shorter than the other screws, as they will be at the level of the obturator foramen.

When drilling for these screws, care should be taken as the obturator vessels are at risk.

### DOUBLE PLATING TECHNIQUE

- Tile described placing a second plate anteriorly if there is no posterior fixation to be placed in vertically unstable patterns (TECH FIG 6).13
- This technique can also be used if insufficient purchase is achieved with initial plate placement.

- In placing the anterior plate, care must be taken in placing screws around the screws of the other plate.
- The same sequence of screw placement should be followed, with the medial screws placed first and subsequent screws placed laterally.

### TECH FIG 6 • Example of double plating described by Tile.

### WOUND CLOSURE

- Once the symphysis is reduced and the plate is in place, a Hemovac is placed in the space of Retzius, between the bladder and the symphysis, and is brought through the rectus fascia.
- After drain placement, the wound is pulse lavaged and the rectus fascia is closed with running heavy absorbable sutures. Care should be taken not to include too many muscle fibers to avoid muscle necrosis.
- Interrupted sutures are used at the distal end to provide a side-to-side closure of the avulsed side.
- The skin is then closed with subcutaneous sutures and staples.

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Setup</th>
<th>It is important to make sure that adequate fluoroscopic AP, inlet, and outlet views can be obtained in the operating room before draping.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reduction</td>
<td>Reduction is confirmed under direct vision as well as on inlet and outlet views of the pelvis. The C-clamp can also be used to maintain reduction before plating if conventional clamps cannot hold the reduction.</td>
</tr>
<tr>
<td>Reduction aids</td>
<td>A second clamp or a ball-spike can be used to assist in reduction if there is difficulty obtaining reduction or holding the symphysis reduced. For instance, in tilt fractures a ball-spike can be used to push against the intact rami while pulling up the pubic body on the fractured side. Again, the C-clamp or an external fixator can be placed to help approximate the pubic bodies to facilitate reduction with a Weber clamp.</td>
</tr>
<tr>
<td>Backup</td>
<td>If fixation is tenuous or if the patient becomes too sick to continue with plating, an external fixator can always be added.</td>
</tr>
<tr>
<td>Screw placement</td>
<td>C-arm is used to confirm placement of screws and confirm that they are not too prominent</td>
</tr>
<tr>
<td>Poor fixation with one plate</td>
<td>Double plating can be used to improve fixation by creating a 90-90 construct.</td>
</tr>
<tr>
<td>Two-hole plate</td>
<td>A two-hole plate should not be used: it allows for rotational instability and has a high failure rate.</td>
</tr>

</table>
POSTOPERATIVE CARE

- Deep vein thrombosis prophylaxis is imperative, as 35% to 60% of patients with a pelvic fracture are at risk. Of these, proximal thrombosis can occur 2% to 10% of the time, and they are at higher risk of developing a pulmonary embolism.  
- With such a high risk of deep venous thrombosis, prophylaxis should consist of a combination of mechanical and chemical means. Venodyne boots or serial compression devices are essential.
- Chemical modalities consist of unfractionated heparin, low-molecular-weight heparin, vitamin K antagonists, and factor Xa indirect inhibitors.
- If patients have a contraindication for chemical prophylaxis secondary to another injury such as a head bleed, an inferior vena cava filter should be considered.
- Our protocol consists of serial compression devices and subcutaneous heparin three times a day preoperatively. Postoperatively patients are started on low-dose Coumadin. Patients remain on Coumadin for at least 6 weeks, depending on their mobility.
- Early mobilization is imperative to prevent comorbid conditions from arising.
  - Once stable fixation is in place, patients should be out of bed to a chair within 24 hours of surgery if their overall condition allows.
  - The patient’s weight-bearing status is highly dependent on the operative surgeon understanding the overall injury pattern of the pelvis.
  - If anterior fixation is used alone, such as for an APC type II injury, patients are made partial weight bearing for about 8 weeks on the operative side.
  - If there is more extensive injury to the posterior pelvis and fixation is required, partial weight bearing should be continued for up to 12 weeks.
  - Patients should be followed routinely with radiographs. On postoperative day 1, before the patient gets upright, AP, inlet, and outlet radiographs should be obtained to assess the reduction and more importantly to be used for comparison for future follow-up radiographs taken at 6 and 12 weeks.

OUTCOMES

- Stabilizing the anterior pelvis improves outcomes, and anatomic alignment allows for ligamentous healing.
- Kellam\(^1\) defined an adequate reduction of anterior symphysis widening as less than 2 cm and reported that when this was obtained in rotationally unstable fractures, 100% of patients returned to normal function. Patients with posterior pathology had poor outcomes, with only 31% reporting normal function.
- Pohlemann et al\(^7\) reported no residual posterior displacement in 95 patients with type B fractures treated with anterior plating. This was associated with an 11% incidence of late pain that occurred after exercise. No patients had pelvic pain at rest.
- Tornetta et al\(^{15,16}\) also reported that APC type II injuries, when treated with anatomic open reduction and internal fixation, have a 96% rate of good to excellent outcomes.
- Pohlemann et al\(^7\) also demonstrated type C injuries radiographically had more residual posterior displacement than type B injuries. Only 33% of these type C patients were pain-free after combined anterior and posterior fixation.
- In general, functional outcomes correlate with the initial displacement of the injury.
- Associated injuries will also dictate outcome. Patients with associated urologic injuries are at risk for urethral strictures, urinary tract infections, and even late infections.
- There is a greater than 90% chance of a good outcome in patients with near-anatomic fixation of the symphysis in APC type II pelvic fractures, and about 96% will be able to return to work within a year of injury.\(^{15}\)

COMPLICATIONS

- Proximal deep vein thrombosis occurs in 25% to 35% of pelvic fractures, so it is imperative to provide proper prophylaxis both mechanically and chemically.\(^6\)
- Plates and screws can fracture or loosen secondary to fatigue due to the physiologic motion that is maintained between the two pubic bodies. This tends to occur after 8 weeks and generally does not affect healing.
- If it occurs earlier and a loss of reduction occurs, then revision osteosynthesis should be considered.\(^4,5,16\)
- Loss of reduction can also occur with widening of the symphysis with and without the plate breaking. Although no data exist, the quality of the initial reduction appears to be the best predictor. Therefore, if a perfect reduction cannot be maintained, additional fixation should be added or activity modification should be implemented postoperatively.\(^5,15\)
- In most series of pelvic fractures reporting on the use of anterior fixation there is a low incidence of anterior wounds developing deep infections.
  - Most resolve with irrigation and débridement and go on to union.\(^2,4,5\)
- Urologic injuries occur in about 15% of pelvic fractures. Urologic complications include late urethral strictures, incontinence, and erectile dysfunction.
  - Early repair of bladder or urethral injuries at the same time of fixation avoids more complex reconstructions, but the rate of late urologic complications is still relatively high.\(^8\)

REFERENCES

DEFINITION

- Pelvic fractures are serious injuries associated with a diverse assortment of morbidities and mortality rates ranging from 0% to 50%.
- Fractures and dislocations of the pelvis involve, in broad terms, injuries to the anterior and posterior structures of the pelvic ring.
  - Injuries to the anterior pelvic ring include symphyseal disruption and pubic body or rami fractures.
  - Injuries to the posterior pelvic ring involve iliac wing fractures, sacroiliac (SI) joint dislocations and fracture-dislocations, and sacral fractures.
- The implications and treatment of damage to these structures vary widely with the broad spectrum of injury patterns, combinations of injuries, and degree of displacement.
- This chapter will focus on treatment of displaced sacral fractures and type 3 SI joint dislocations.

ANATOMY

- The pelvis is a ring structure composed of the two hemipelvises, or innominate bones, and the sacrum. Each innominate bone is formed as the result of fusion of the three embryonic bony elements: the ilium, the pubis, and the ischium (FIG 1A).
- The two innominate bones are joined anteriorly at the pubic symphysis, a symphyseal joint. Posteriorly, the two innominate bones articulate with the wings, or alae, of the sacrum via the strong SI joints to complete the ring (FIG 1B).
- The sacrum represents the terminal structural segment of the spinal column that connects the pelvis and extremities to the trunk and spine.
- As the sacrum is essentially a spinal element, it is subject to segmentation abnormalities and dysmorphisms.
  - Most commonly, segmentation anomalies such as a lumbarized S1 and a sacralized L5 will be present (FIG 2).
  - The only true way to be sure which defect, if any, is present, is to count down from the first thoracic vertebrae, which is the first vertebra to have transverse processes that are inclined cephalad.
  - As a general rule of thumb, however, the top of the iliac crest is usually at the same level as the L4/5 disc space. This rule can be used to judge the presence of dysmorphism (see Fig 2A).
- These issues are pertinent to interpretation of the radiographic landmarks required to safely place iliosacral screws (see later).
- Being wedge-shaped, the sacrum forms a keystone articulation with the innominate bones.
- By virtue of this shape and their orientation, the SI joints are inherently unstable and the maintenance of posterior pelvic ring integrity is wholly dependent on the support provided by the ligamentous structures for stability (see Fig 1B and FIG 3).
- With axial loading, the natural tendency is for each hemipelvis to externally rotate and translate in a cephalad and posterior direction. The pelvic ligaments are structured and positioned to re-
The symphyseal ligaments (themselves contributing no more than 15% to pelvic ring stability), the sacrotuberous ligaments, and the sacrospinous ligaments resist external rotation.13,32

The bladder is immediately posterior to the pubic bodies and symphysis, separated only by a thin layer of fat and the potential space of Retzius.

The intimate relationship of the L5 nerve root to the superior aspect of the sacral ala as it courses to join the lumbosacral plexus is a key anatomic feature that must be kept in mind during reduction and stabilization of posterior pelvic ring injuries (FIG 4).

The superior gluteal artery is immediately lateral to the inferior aspect of the SI joint as it arises from the internal iliac artery to exit the greater sciatic notch with the superior gluteal nerve. The obturator nerve and artery course along the quadrilateral plate (medial wall) of the acetabulum as they exit the superior and lateral quadrant of the obturator foramen (see Fig 4).
PATHOGENESIS
■ Because the SI ligaments are the most resilient in the human body, SI dislocations occur purely as a result of high-energy traumatic injuries.
■ Anteroposterior compression of the pelvic ring causing external rotation of the innominate (which may or may not be coupled with a vertical shearing force) is the most common cause of SI joint dislocation.
■ Sacral fractures, however, can occur in three distinctly different situations.
  ● Insufficiency fractures of the sacrum arise secondary to failure through excessively osteoporotic or osteopenic bone.
  ● Stress fractures of the sacrum result from fatigue and cyclic failure of normal bone in high-level athletes or military recruits.
  ● Traumatic disruptions result from high-energy lateral or anteroposterior compression or vertical shear injuries such as (in order of decreasing frequency) motorcycle crashes, auto–pedestrian collisions, falls from height, motor vehicle accidents, or crush injuries.5,32

NATURAL HISTORY
■ Pelvic fractures occur in at least 20% of blunt trauma admissions, most frequently in young males.
■ They can result in small insignificant fractures of the pubic rami with no compromise of pelvic ring stability, or major injuries and disruptions that can be associated with life-threatening bleeding or visceral injury.
■ The pelvic ring encloses the true pelvis (organs contained below the pelvic brim, extraperitoneal) and the false pelvis (organs contained above the pelvic brim, both peritoneal and retroperitoneal).
■ The most commonly associated injuries to structures contained within the true pelvis are the internal iliac arterial and venous systems and branches, the bladder (20%) and urethra (14%), the lumbosacral plexus, and the rectum and vaginal vault (open pelvic fractures).
■ Injuries to structures within the false pelvis as a direct result of the pelvic fracture are uncommon, but severe iliac wing fractures with abdominal wall disruption can result in intestinal injury and even entrapment.
■ Morbidity and mortality from pelvic fractures can be high and are most commonly secondary to pelvic hemorrhage.
  ● The mortality rate associated with pelvic fracture with an associated bladder rupture approaches 35% in some series, and the mortality rate of open pelvic fractures involving the perineum used to be as high as 50%.
  ● Fortunately, this has decreased to about 2% to 10% with the liberal use of diverting colostomies and more advanced stabilization techniques.
  ● Neurologic injury to the lumbosacral plexus can lead to significant sensorimotor dysfunction involving the extremities, bowel, bladder, and sexual functions.
  ● Because of these associated neurovascular and visceral injuries, pelvic fractures often result in prolonged recovery periods, significant chronic pain, permanent disability, and loss of psychological and socioeconomic structure.5,9,21–29

PATIENT HISTORY AND PHYSICAL FINDINGS
■ Any patient presenting with a history of trauma or satisfying criteria for a Trauma Alert in the emergency department should be suspected of having a pelvic fracture until otherwise ruled out by radiologic and physical examination.
■ The physical examination should follow the primary and secondary survey of the Advanced Trauma Life Support protocol.1
■ Examination of a patient suspected of having a pelvic fracture should be divided into the examination of the abdomen, pelvic ring, perineum, rectum, vagina, and lower extremities.
■ The abdominal examination should elucidate:
  ● Tenderness, fullness, or rigidity
  ● Abdominal wall disruptions, defects, or open wounds
  ● Flank ecchymosis
  ● Presence of internal degloving or a Morel-Lavalle lesion (separation of the subcutaneous tissues from the underlying fascia). This can be recognized by subcutaneous fluctuance or a fluid wave and, later, extensive ecchymosis.
■ The rectal and vaginal examination should consider:
  ● The position of the prostate (a high-riding prostate may be a sign of urethral injury)
  ● Palpable bony fragments perforating the rectal or vaginal mucosa
  ● Defects or tears in the wall of the rectum or vagina indicating possible bony penetration
  ● Rectal or vaginal bleeding indicating possible tears or bony penetration
  ● Urethral bleeding at the meatus indicating possible urethral or bladder disruption
  ● Scrotal or labial swelling and ecchymosis indicating pelvic hemorrhage (FIG 5)
  ● Rectal tone, perianal sensation, voluntary sphincter control, and bulbocavernosus reflex to assess for the presence of cauda equina syndrome or lower sacral nerve root injury
■ Examination of the pelvic ring and extremities should focus on the following key factors:
  ● Palpable internal or external rotation instability of the pelvic ring with manually applied anteroposterior and lateral compressive forces on the iliac wings and crests
  ● Leg-length discrepancy with asymmetrical internal or external rotation
  ● Neurologic status in patients able to comply can be assessed as follows:
    ● L1/2: iliopsoas (hip flexors) and upper anterior thigh sensation
    ● L3/4: quadriceps (knee extensors) and lower anterior thigh and medial calf sensation
    ● L5: extensor hallucis longus, digitorum longus (toe dorsiflexion), peroneal eversion (although this can have a
strong L4 component) and lateral calf and dorsum of foot sensation

- S1: gastrocnemius complex (ankle plantarflexion) and posterior calf sensation
- S2/3: flexor hallucis and digitorum longus (toe plantarflexion) and sole of foot sensation

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

**Plain Radiographs**

- The standard anteroposterior (AP pelvis) view should be part of the initial trauma series screening. With enough experience, many of the injuries to the posterior pelvic ring can be diagnosed with this single projection (FIG 6A,B).
- A good AP radiograph should have the pubic symphysis co-linear with the sacral spinous processes.
  - This allows side-to-side comparison of bony landmarks to aid in diagnosis of subtle displacements of the sacrum or SI joint.
- The cortical density of the pelvic brim and iliopectineal line should be traced back to its intersection with the lateral margin of the sacral ala.
  - This intersection should be at the same level (usually the inferior margin of the S2 foramen) bilaterally.
- Asymmetry in the SI joint space and the appearance of the sacral foramina should alert the surgeon to the presence of an SI joint dislocation or sacral fracture.
- Fractures of the L5 transverse process may be a clue to a vertical shear injury that has avulsed the transverse process via the iliolumbar ligament.
- Symphyseal diastasis or displaced rami fractures should alert the examiner to additional injuries in the posterior ring, even though they may not be readily apparent on first glance.

- The inlet projection is taken with the x-ray beam directed caudally about 45 degrees to the radiographic film.
- A true inlet view of the pelvis, however, may require variations on this degree of angulation because of the normal variations in sagittal plane pelvic obliquity.
- This view simulates a direct view into the pelvis from above along its longitudinal axis (FIG 6C,D).
- The inlet view is helpful in imaging:
  - External or internal rotation of the hemipelvis
  - Opening of the SI joint or an impaction fracture of the sacrum
  - “AP” displacement or translation of the hemipelvis (see below)
- The outlet projection of the pelvis is obtained by directing the x-ray beam about 45 degrees cephalad to the radiographic film.
- This view simulates looking at the sacrum and SI joints directly en face (FIG 6E,F).
- The outlet view is helpful in imaging:
  - Cephalad or “vertical” shift of the hemipelvis
  - Sacral fractures relative to the foramina
  - Flexion–extension deformity of the hemipelvis
- These radiographs are taken at about 45 degrees to the long axis of the patient’s body.
- Therefore, a given amount of translation or displacement seen on the inlet or outlet view is in fact the sum of displacement vectors in both the coronal and axial planes. For example, “posterior” shift seen on the inlet projection is in fact a combination of both posterior and cephalad translation.
- Another important point to bear in mind is the appearance of the sacrum on the AP projection.
- If one sees a paradoxical inlet view of the upper sacrum and outlet view of the distal sacrum, a lateral radiograph and CT scan with sagittal reconstruction must be performed to rule out an occult sacral fracture-dislocation (a U-shaped
sacral fracture otherwise known as spinal-pelvic dissociation; FIG 7).

Computed Tomography

CT is imperative in any suspected pelvic ring injury.
- As the pelvis is a ring structure, any disruption in one location (no matter how seemingly insignificant) must (by virtue of ring structure mechanics) be accompanied by disruption in another location.
- Three-millimeter axial sections (or 3 mm of vertical travel per 360-degree rotation of the gantry in a spiral CT) are recommended to disclose the majority of significant injuries and to allow for good-quality three-dimensional reconstructions (FIG 8).

Retrograde Urethrography and Cystography

- Retrograde urethrography and cystography are mandatory in pelvic fractures with ring disruption to rule out urethral and bladder injury.
- The Foley catheter is partially inserted into the urethra, and the balloon is inflated with 2 to 3 mL of sterile saline to occlude the urethra. Ten to 15 mL of water-soluble contrast is then injected into the urethra and the outlet view of the pelvis is repeated.
- If no extravasation is seen, the catheter is advanced into the bladder with injection of a further 300 mL of water-soluble contrast to rule out a bladder rupture. If no contrast extravasation is noted, the bladder is drained with the Foley, and any residual dye is noted.
- If passage of the catheter is not possible or there is a tear of the urethra or bladder neck, suprapubic catheterization should be performed well above the umbilicus if possible (to avoid contamination of potential future anterior pelvic operations).

Pelvic Angiography

- Angiography is indicated in patients with persistent hemodynamic instability despite:
  - Adequate volume resuscitation
  - Other sources of hemorrhage being ruled out (abdomen, thorax, and long bone fractures)
  - Attempts to “close” the pelvic ring (see below) have failed to stop pelvic hemorrhage
- Most cases of pelvic hemorrhage (85%) arise from venous bleeding, which is not amenable to angiographic embolization.
- Arterial bleeding is usually from branches of the internal iliac system (median sacral, superior gluteal, pudendal, or obturator arteries; FIG 9).
If diagnostic peritoneal lavage is being performed to rule out abdominal hemorrhage, then it must be performed above the umbilicus and arcuate line to avoid false-positive results from pelvic hemorrhage.

NONOPERATIVE MANAGEMENT

- As a general rule, traumatic type 3 SI dislocations should not be managed nonoperatively.
- Progressive cephalad displacement of the hemipelvis will result in pelvic malunion. Leg-length inequality, chronic mechanical low back and buttock pain, pelvic obliquity with sitting imbalance, and dyspareunia are common complaints when the hemipelvis and ischial tuberosities are positioned medially or cephalad.
- For patients in extremis or those with sepsis or critical medical comorbidity, nonoperative therapy may be the only option.
- In these cases, the pattern of deformity dictates the maneuvers to be used to minimize the malunion.
- Patients with any evidence of vertical instability should be placed into balanced longitudinal skeletal traction in an attempt to reduce or prevent further cephalad displacement.
- Distal femoral traction is preferable.
- Patients with external rotation deformity of the pelvic ring (ie, “open book” pelvis) should be initially treated with some form of temporizing pelvic binder (ie, the T-POD pelvic binder, Bio-Cybernetics, LaVerne, CA) or an external fixation clamp.
- This helps to reduce the external rotation deformity, stabilize the pelvic hemorrhage and clot, and improve patient comfort in the acute resuscitative period.²
- Ideally, circumferential devices such as pelvic binders (FIG 10) should be applied over the greater trochanters, and frequent skin checks are mandatory to prevent full-thickness pressure ulceration. As such, they are rarely if ever indicated for definitive treatment. Anterior pelvic external fixators can be applied either in the iliac crest or the anterior inferior iliac spine and supra-acetabular bone.
- Anterior external fixators are good for controlling external and internal rotation of the anterior pelvic ring. Thus, the surgeon may elect to use them definitively if the SI joint is disrupted only through the anterior SI ligaments (a type 2 injury with no vertical or sagittal plane instability) or with certain lateral compression injuries where the sacral fracture is stable by virtue of its impaction.
- By themselves, however, anterior external fixators are not effective in controlling the posterior pelvic ring, and if applied incorrectly they can make some pelvic deformities worse.¹⁶,³⁰
- For external fixation control of the posterior ring, external C-clamps and pelvic clamps are used on occasion, but expertise is required in their use to prevent serious complications from misplacement.⁸,¹⁸
- In contrast to SI joint dislocations, most traumatic sacral fractures can be treated successfully with nonoperative care.
- Although vertical shear sacral fractures represent the far end of the spectrum of unstable sacral fractures needing operative stabilization, impacted sacral fractures resulting from lateral compression mechanisms can be relatively stable injuries (FIG 11A,B).
- If the radiographic and CT scanning evaluation reveals an impacted sacral alar fracture without significant displacement in other planes, a trial of nonoperative therapy is warranted. The patient must comply with the weight-bearing restrictions and close radiographic follow-up to prevent gradual shift that will result in a pelvic malunion and leg-length inequality with sitting imbalance (FIG 11C).
- Often, the presentation of the patient in bed can help to predict success with nonoperative treatment of impacted sacral fractures.
- Patients able to roll in bed on their own and help with hygienic care with only minimal or moderate discomfort often have a relatively stable pelvis and will be able to mobilize with physical therapy.
- Some patients, however, will not be able to tolerate even log-rolling in the bed with nursing care.
- They may be found on examination under anesthesia to have an unstable pelvis despite innocuous-appearing imaging studies.
If a patient with an impacted sacral fracture is deemed to be a candidate for nonoperative treatment, he or she is mobilized with physical therapy in 3 to 5 days so long as all other injuries permit.

- The patient is instructed in touch-down weight bearing on the affected extremity.
- If the patient can successfully mobilize, then AP, inlet, and outlet radiographs are repeated within a week to assess for any further displacement and increasing leg-length inequality.
- If no further displacement occurs, the patient is instructed to continue touch-down weight bearing for another 8 to 10 weeks, with repeat radiographs every 4 weeks.

**SURGICAL MANAGEMENT**

**Treatment Options**

**Iliosacral Screws**

- In general, all complete SI joint dislocations and unstable displaced nonimpacted sacral fractures should be treated with operative stabilization.
- The choice of fixation in most instances for both SI joint dislocations and sacral fractures will be with iliosacral screws (SI screws).
- Biomechanical studies have validated the strength of this technique in comparison to more traditional anterior SI plating and transsacral bars and plates.\(^{11,26}\)

- Also, SI screws can be applied with the patient in either the prone or supine position, and in either an open or closed percutaneous fashion.
- SI screw placement, however, does require an exacting knowledge of the radiographic correlates of anatomic landmarks to prevent neurologic and vascular injury.\(^{3,6,13,22,31,33}\)
- Transforaminal sacral fractures with comminution and vertical instability treated with standard SI screw fixation alone may be suboptimal and have a high reported failure rate.
- In these instances, the surgeon may elect to place alternate forms of fixation to augment the SI screw (such as with transsacral screws or with some form of spinal pelvic construct to better resist the tendency for vertical displacement).\(^{12,24,27}\)

**Spinal Pelvic Fixation**

- Also known as *lumbopelvic fixation* and *triangular osteosynthesis*, spinal pelvic fixation is done to augment an SI screw for a very unstable posterior ring injury that has been reduced and temporarily stabilized but remains at risk for failure of fixation and subsequent redisplacement.
- This usually arises in the case of extensively comminuted transforaminal sacral fractures.

**Sacral Nerve Decompression**

- Sacral nerve decompression is indicated in either of two situations:
  - The patient has a neurologic deficit attributable to sacral radiculopathy and preoperative imaging shows fracture fragments within the sacral foramen.
  - The patient is neurologically intact, but preoperative imaging studies disclose a large bone fragment within the foramen that during reduction will further compress the nerve root and stenose the foramen, resulting in iatrogenic nerve root injury (**FIG 12**).

**Zone 3 Sacral Fractures**

- Vertically oriented zone 3 sacral fractures are usually the result of wide anteroposterior compression forces and are associated with anterior ring disruption.
- Generally, they can be treated with internal rotation and anterior ring fixation alone.
- If residual sacral gapping persists, however, an SI screw with short threads can be placed into the contralateral S1 body to close the residual gap.

**U-Shaped Sacral Fractures**

- Otherwise known as spinal-pelvic dissociation, this fracture is essentially a sacral fracture-dislocation.
- It tends to occur through the vestigial disc space and result in kyphosis.

---

**FIG 11 • A,B.** Impacted sacral fracture from lateral compression mechanism with internal rotation. **C.** Nonoperative treatment of vertical shear sacral fracture with resultant malunion and leg-length inequality.

**FIG 12 •** Axial CT scan of a sacral fracture showing large intraforaminal bony fragment.
These fractures can be easily missed on the standard AP pelvis view (FIG 13A) and even axial CT scans, but they are quite evident on the sagittal CT reconstruction (FIG 13B).

These injuries generally do not result in pelvic ring instability, as the SI joints and distal surrounding sacrum are intact; they are more commonly associated with spinal instability. They can be associated with cauda equina syndrome and significant spinal instability and should be treated by an experienced spinal surgeon.

Although some trauma surgeons have advocated bilateral SI screw fixation alone for these injuries, they more commonly require reduction, decompression, and some form of posterior lumbopelvic fixation to control kyphotic deformity.

Preoperative Planning

Proper preparation and preoperative planning for any major pelvic surgery are mandatory.

These operations can be associated with prolonged anesthetics, lengthy prone positioning, extensive blood loss, and complex reduction maneuvers that can pose serious risk to the patient with other medical or traumatic comorbidities.

Having a detailed understanding of the deformity and the reduction and fixation strategy can help to significantly decrease operative time and blood loss.

All patients should have had anticoagulation started within 24 hours of admission.

If there are contraindications to anticoagulation, inferior vena caval filter placement should be requested.

If an open reduction is predicted to be necessary, waiting for 3 to 5 days is prudent to allow the pelvic clot to stabilize and diminish intraoperative bleeding.

Patients should have at least three units of typed and cross-matched blood on hold.

The surgery should be booked semielectively if possible, with a surgical team that is familiar with complex pelvic surgery.

Positioning

Patients should be positioned on a radiolucent table that allows traction to be applied in some fashion.

Regarding the standard OSI (Orthopaedic Systems Inc., Union City, CA) fracture table with the perineal post, adequate caudal translation cannot be obtained as long as the perineal post is in place because the ischial tuberosity and pubis tend to abut the post, preventing further caudal translation of the hemipelvis.

This problem can be overcome by stabilizing the contralateral extremity in a traction boot without applying traction to provide some vertical support for the contralateral side while traction is applied to the affected extremity.

Another alternative in cases with severe vertical displacement is to rigidly fix the contralateral pelvis to the OR table with Schanz pins and an external fixator with a frame supplied by OSI.

Patient positioning will be in either the prone or supine position, depending on the surgeon’s assessment of the ability to achieve reduction using closed (supine) or open (prone) means.

In some cases, initial reduction of the anterior pelvic ring will facilitate reduction of the posterior ring, allowing the entire procedure to be performed in the supine position.

However, an imperfect reduction of the anterior pelvic ring and subsequent rigid stabilization may actually impair reduction of the more important posterior ring. In this case, anterior fixation would have to be removed to allow for an exact reduction of the posterior ring.

For the patient positioned in the prone position (FIG 14), the surgeon must ensure proper padding and support for the chest to allow adequate ventilation.

FIG 13 • U-shaped sacral fractures can be difficult to detect on standard AP pelvis views (A) but are more evident on sagittal CT reconstruction (B).

FIG 14 • Positioning and setup of patient for posterior approach and reduction of sacral fracture or sacroiliac joint dislocation. Note the pelvis hanging freely, traction setup, and rigid stabilization frame on contralateral stable hemipelvis.
It is preferable to use longitudinal chest rolls that come short of the pelvis, allowing the lower trunk to hang freely and not rest on the anterior superior iliac spine. If the pelvis is permitted to rest on the anterior superior iliac spine, posterior translation of the unstable hemipelvis may result or reduction may be impaired. The extremity ipsilateral to the unstable hemipelvis should be draped free to allow longitudinal traction and internal–external rotation. It should be placed in either boot or skeletal (distal femoral or proximal tibial) traction that allows for rotation and abduction–adduction. Extension of the hip and extremity will help to indirectly reduce the hemipelvis as well, since some degree of flexion deformity exists in vertically displaced pelvic fractures. Draping of the operative field should include the entire flank on the affected side. The field should continue to include the buttoc and upper thigh, with free draping of the affected extremity. The natal cleft and contralateral buttock are excluded from the field. For the patient positioned in the supine position, a small folded sheet or pad should be placed under the sacrum or buttock on the affected side to lift the pelvis away from the table. Again, the affected extremity should be placed into traction to aid in reduction, as detailed above. If there is posterior displacement of the hemipelvis, placing the bump under the buttock will help to anteriorly translate the pelvis when traction is applied. If there is anterior translation of the hemipelvis, placing the bump directly midline will help to lift the pelvis away from the table and also let the affected hemipelvis hang freely to allow posterior translation during reduction maneuvers.

**Approach**

Approach to the SI joint can be either anterior or posterior. If significant displacement exists and a difficult open reduction is predicted, the posterior approach should be chosen. The anterior approach does not afford good visualization of the entire SI joint, only the superior aspect at the top of the ala. Also, placement of reduction clamps anteriorly across the SI joint, while possible, is cumbersome and places the L5 nerve root at risk. The anterior approach to the SI joint is advocated only in situations in which:
- The soft tissues do not permit the posterior approach.
- The patient will not tolerate prone positioning because of poor pulmonary status.
- A close-to-anatomic closed reduction of the SI joint can be obtained with traction and manipulation and only minor adjustments need to be made.

**POSTERIOR APPROACH**

For the posterior approach to the SI joint dislocation and sacral fracture, the incision is vertical and paramedian, centered directly over the involved SI joint. The incision is not carried directly over the bony prominence of the posterior superior iliac spine; rather, it is placed just medial to the posterior superior iliac spine (TECH FIG 1A). The tissues that bridge the SI joint posteriorly in the intact state include the lumbodorsal fascia, the transverse fibers of the gluteus maximus (TGM), the paraspinal...
erector spiniae muscles, the iliolumbar ligament, and the posterior SI ligaments (TECH FIG 1B).

- With SI joint dislocations, some or all of these fascial, muscular, and ligamentous layers may be completely disrupted, and no further dissection is needed.
- Often, however, to visualize the inferior aspect of the SI joint posteriorly, the TGM needs to be mobilized. The TGM attachment to the sacral spinous processes and thoracolumbar fascia is released and the TGM is reflected laterally and inferiorly to expose the inferior aspect of the SI joint. To prevent wound complications, the attachment and origin of the gluteus maximus must be preserved.

- Occasionally some of the lumbodorsal fascia will need to be released from the posterior iliac crest.
- This allows dissection up over the superior aspect of the SI joint and sacral ala to permit digital palpation to assess reduction of the anterior SI joint.
- Once exposure is complete, it is usually necessary to evacuate a significant amount of blood clot and hematoma from the joint.
- On occasion, loose fragments of denuded articular cartilage will require removal.
- Routine removal of articular surfaces for a primary SI joint fusion is not performed, however, unless there is significant cartilaginous destruction to begin with.
- During removal of blood clot and debris, specific attention must be paid to the superior gluteal vessels and the internal iliac vascular system.
- Removal of clot may restart arterial bleeding that was initially controlled by tamponade and spasm, or direct iatrogenic injury may occur with dissection through the fracture hematoma and clot.
- All sacral fractures that necessitate an open reduction require a posterior approach.
- Anterior approaches are not recommended as it is not possible to dissect onto the anterior aspect of the sacrum without posing excessive risk to the lumbar-sacral nerve roots and iliac vessels.
- The posterior approach for sacral fracture reduction varies depending on the fracture location and the need for sacral nerve root decompression.
- In general, however, most sacral fractures and foraminal decompressions can be performed through the same paramedian approach as described above for SI joint dislocations. The only alterations in technique would be as follows:
  - Subperiosteal elevation of the paraspinal muscles from the dorsal aspect of the sacrum to the spinal processes is required to expose the whole posterior surface of the sacrum (TECH FIG 1C).
  - Proximal extension in the intermuscular plane of the paraspinal muscles exposes the L4–L5 facet joint in the manner described by Wiltse, if a spinal pelvic construct is to be applied.

Open Reduction of the SI Joint and Sacrum via the Posterior Approach

- Reduction of the dislocated SI joint is complex and requires a good knowledge of the three-dimensional anatomy of the sacrum, ilium, and SI joint.
- Although some anteroposterior translation and lateral–medial translation may be necessary to reduce the SI joint, longitudinal traction is the single most important indirect maneuver to perform.
- Adequate longitudinal traction can be assessed intraoperatively with direct visualization, digital palpation, and the image intensifier.
- Reduction of the superior aspect of the SI joint can be assessed with digital palpation, ensuring that the superior–anterior aspect of the SI joint is flush.
- Final confirmation with inlet, outlet, and AP radiographs will help disclose subtle rotational deformities not appreciated by direct visualization or palpation.
- Only once adequate length has been restored can the need for additional anteroposterior or medial-to-lateral translation be assessed.
- Fine-tuning of the SI joint reduction will require the placement of one or two reduction clamps to medially translate and internally rotate the hemipelvis. Large pointed reduction clamps (eg, Weber clamp or offset Matta clamps) are used.
- Posteriorly, a clamp can be placed over the sacral spinous process or into the posterior cortex of the sacrum inferiorly and into the cortical bone of the medial aspect of the greater sciatic notch. This can help close the inferior aspect of the SI joint (TECH FIG 2A).
Chapter 3  ORIF OF THE SACROILIAC JOINT AND SACRUM 497

• The anterior approach to the SI joint uses the upper limb of the Smith-Peterson approach, taking the external oblique fibers off the iliac crest and elevating the iliacus muscle subperiosteally from the inner table of the ilium.

• When the SI joint is encountered, careful mobilization of the tissue on the sacral ala using a blunt periosteal elevator and finger dissection helps to move the L5 nerve root medially out of harm’s way.

• A second clamp can be used superiorly, with one tine placed carefully over the top of the joint onto the sacral ala anteriorly and the second tine placed just lateral to the posterior superior iliac spine (TECH FIG 2B,C).

• Alternatively, this second clamp can be placed through the greater notch, with one tine on the sacral ala and the other on the posterior cortex of the ilium (TECH FIG 2D,E).

• Once this tissue is mobilized and the sacral ala is seen under direct vision, a sharp Hohmann retractor is driven into the alar cortex and used to protect the L5 nerve root, which lies medial (TECH FIG 3).

Open Reduction of the SI Joint via the Anterior Approach

• Once the SI joint and sacral alae have been exposed, reduction can be carried out.

• Similar to the posterior approach, longitudinal traction is applied with internal rotation of the extremity.

• If there is wide diastasis of the SI joint and symphysis, the surgeon may elect at this stage to expose the symphysis and temporarily reduce it with a clamp to aid in internal rotation and reduction.

• However, permanent fixation of the symphysis at this time is not indicated, as it may impede anatomic reduction of the SI joint by limiting motion of the unstable hemipelvis.

• If open reduction of the symphysis is performed, it is held temporarily with a clamp so that it can be removed or adjusted if the SI joint does not reduce satisfactorily.

• Should persistent diastasis of the SI joint exist despite these indirect maneuvers, a Verbrugge or Farabeuf reduction clamp can be used to complete the reduction.

• A single cortical screw is placed on either side of the SI joint into the ilium and sacral ala, respectively.

• The heads of the screws are left proud off the cortex, allowing the reduction clamp to engage the screw heads.

• The clamps can be rotated and twisted in any direction while closing the gap to achieve reduction of the joint (TECH FIG 4).

• Alternatively, an offset reduction clamp or King Tong reduction clamp can be placed on the ala and external iliac wing, as in Techniques Figure 2B, but from the front.
**TECH FIG 4** • Farabeuf pelvic reduction clamp reducing the sacroiliac joint from the anterior approach using the two-screw technique.

**PLACEMENT OF ILIOSACRAL SCREWS**

**Entry Points**
- Large cannulated partially threaded screws are used (7.3 or 8.0 mm).
- The entry point externally is typically 10 to 20 mm anterior to the crista glutea two thirds of the way from the iliac crest (posterior superior iliac spine) to the greater sciatic notch, or 2 cm up and 2 cm posterior to the notch (TECH FIG 5A).
- Percutaneously, the external landmark for choosing the correct entry site is the point of intersection between a line extending proximally from the greater trochanter and a horizontal line extending laterally from the posterior superior iliac spine (TECH FIG 5B).
- In percutaneous procedures, the surgeon must be wary of injury to the superior gluteal neurovascular bundle since the entry point is close to the neurovascular bundle as it exits the greater sciatic notch.4,23
- “Safe” placement is maximized by careful attention to radiographic bony landmarks.6,33

**Safe Placement and Trajectory**
- The three critical projections for placing an SI screw are:
  - The lateral projection to center the guidewire on the sacrum anterior to the canal and to ensure that the guidewire is below the iliac cortical density and sacral alar slope to prevent injury to the L5 nerve root (TECH FIG 6A).
  - The outlet projection to ensure that the guidewire passes above the S1 sacral foramen (TECH FIG 6B).
  - The inlet view to ensure that the guidewire is at the proper trajectory and coming to rest in the anterior aspect of the sacral body–promontory for maximal purchase (TECH FIG 6C).
  - The surgeon should be attentive to sacral dysmorphism and segmentation defects that give rise to altered anatomy, such as lumbarized S1 or sacralized L5 vertebral bodies.
  - The case shown in TECHNIQUES FIGURE 7A,B demonstrates a unilateral sacralized L5 on the right. The left side is normal. The iliac crest is in line with the L4–5 disc space.
  - The safe corridor for the SI screw is between the valley of the ala anteriorly (L5 nerve root), the sacral canal posteriorly (cauda equina), and the sacral foramen inferiorly (S1 nerve root).
  - In the normal situation (no segmentation abnormality), the corridor is well defined (TECH FIG 7C), but in the case of a sacralized L5, the safe corridor is either exceedingly narrow or nonexistent (TECH FIG 7D,E).
  - If this abnormality is not recognized and an SI screw is placed into L5 assuming it is S1, the L5 nerve root is likely to be injured.
  - If the surgeon is unsure, the lateral projection with the iliac cortical densities is key in determining the correct level to place the screw, since they are constant with their relationship to S1 even in segmentation abnormalities (TECH FIG 7F).
  - TECHNIQUES FIGURE 7G shows a reduced SI joint dislocation with a safely placed SI screw.

For SI joint dislocations, the screw trajectory should be from inferior to superior on the outlet view, and from
posterior to anterior on the inlet view (perpendicular to the plane of the SI joint).

- For sacral fractures, the screw trajectory should be straight across from lateral to medial on the inlet view (perpendicular to the fracture plane).
- The tip of the SI screw should come to rest in the contralateral side of the S1 body and promontory.
- Carrying the screw into the ala provides weaker purchase secondary to poor bone quality and increased risk to the contralateral L5 nerve root.

- In situations of comminuted transforaminal sacral fractures, the theoretical risk of overcompression and iatrogenic sacral nerve root injury exists. To gain stability with the construct and avoid a nonunion, some compression is necessary, however.
- If this risk exists, sacral nerve root decompression should be performed before placing the SI screw, or an alternative form of fixation such as spinal pelvic fixation or a transsacral screw should be placed.

**TECH FIG 6**

A. Lateral projection of pelvis showing the iliac cortical density (ICD) or sacral alar slope line. The tip of the sacroiliac screw and guidewire must be below this line when the screw is at the level of the foramen on the outlet projection. Outlet (B) and inlet (C) projection showing path of iliosacral screw for sacroiliac joint dislocation.

**TECH FIG 7**

Outlet projection (A) and three-dimensional reconstruction (B) showing the segmentation anomaly (in this case a unilateral sacralized L5). C. Safe corridor for placement of an S1 iliosacral screw into the ala of S1. D,E. Lack of safe corridor into “S1” demonstrated on this axial CT of the patient with the unilateral sacralized L5. On some cuts and the lateral projection this may appear as S1 when it is in fact L5. There is no safe corridor at this level. F. Safe placement of an iliosacral screw into S1 under the iliac cortical densities (red arrow). G. AP projection demonstrating a reduced sacroiliac joint with a well-placed sacroiliac screw.
SPINAL PELVIC FIXATION

- Through a posterior approach as described above, the L4–5 facet joint is exposed, taking care not to disrupt the capsule.
- A 6.2-mm titanium Schanz screw is placed into the L5 pedicle, with the entry point at the junction of the transverse process and the lateral border of the facet joint.
- A second Schanz screw is placed into the ilium at the posterior superior or inferior iliac spine, and then directed between the inner and outer tables of the ilium.
- The trajectory should be aiming for the ipsilateral greater trochanter as an external landmark. The screw should be directed to pass through the region of the sciatic buttress as seen on the iliac oblique view.
- Placement out of the SI joint and within the confines of the inner and outer tables can be confirmed on the obturator and iliac oblique views (TECH FIG 8A,B).
- These two screws are then connected with fixed-angle clamps and a 5.0-mm rod, supplementing the SI screw to resist vertical displacement (TECH FIG 8C).
- Sacral fracture reduction and fixation with clamps and an SI screw as described above should be performed before placing any spinal pelvic construct.
- This avoids rigid fixation with residual sacral gap and subsequent nonunion or delayed union.

SACRAL NERVE ROOT DECOMPRESSION

- In most transforminal fractures, the incriminating fragment of bone can be found and removed by working directly through the fracture in the sacrum.
- A laminar spreader can be placed into the fracture to spread the respective portions of the fracture.
- After the clot is removed, careful dissection along the exposed surface of the medial sacral fragment will disclose some portion of the foramen.
- Tracing the nerve root anteriorly will usually lead to the bone fragment.
- Occasionally, a Kerrison and pituitary rongeur will be needed to remove some portion of the sacral lamina to find the nerve root, so these instruments should always be readily available.

### POSTOPERATIVE CARE

- Provided that all other injuries permit, the patient is mobilized the first postoperative day.
  - The patient is instructed to be touch-down weight bearing on the ipsilateral extremity for 10 to 12 weeks for SI dislocations and sacral alar fractures stabilized with SI screws.
  - Patients with spinal pelvic fixation can be allowed to bear full weight within 4 to 6 weeks.
  - All patients are given a regimen of pelvic, core trunk, hip, and knee range-of-motion exercises.
  - Common early postoperative problems in patients with severe pelvic fractures include ileus and urinary retention; these need to be addressed early.
    - The Foley catheter is usually not removed until the patient can mobilize well with physical therapy.
    - Diet is not advanced until flatus and normal bowel sounds have returned.
    - Anticoagulation is administered in all patients for 6 weeks, with low-molecular-weight heparin or Coumadin for deep venous thrombosis and pulmonary embolism prophylaxis.

### OUTCOMES

- Outcome studies after fixation of pelvic fracture-dislocations are difficult to interpret because of poor follow-up, heterogeneity of the injury pattern, associated visceral and neurologic injury, and the lack of reliable outcome measures for pelvic ring injuries.
- Improved short-term patient outcomes with early stabilization and mobilization as well as numerous reports citing improved outcomes with anatomic reduction of the posterior ring continued to provide the impetus to develop more rigid and stable posterior fixation constructs.
- Earlier outcome studies support the position that the long-term functional results are improved if reduction with less than 1 cm of combined displacement of the posterior ring is obtained, especially with pure dislocations of the SI complex.
  - Fractures of the posterior ring, as opposed to pure SI dislocations, tend to display superior outcomes, presumably because bony healing can restore initial strength and stability.
  - In contrast, SI dislocations rely purely on ligamentous healing and scar formation; as a result, these patients tend to have worse functional outcomes in the short term and long term with pain and ambulation compared to patients with other injury patterns.
- More recent detailed clinical outcome studies have shown that with current fixation techniques, many patients continue to have poor outcomes with chronic posterior pelvic pain despite seemingly anatomic reductions and healing, with less than 50% returning to previous level of function and work status.
- This disparity in results is likely related to multiple confounding factors, such as:
  - Poor financial and psychosocial and emotional status of trauma patients
  - Extensive soft tissue damage and associated long bone and extremity fractures
  - Associated neurologic, visceral, and urogenital injuries, resulting in dyspareunia, sexual dysfunction, and incontinence
  - Prolonged recovery and rehabilitation time, with loss of job, home, and family roles
COMPLICATIONS

- Blood loss and the need for transfusion is common with any open procedure on the posterior pelvic ring, particularly with open reduction of the SI joint and sacral fracture, where injury to the superior gluteal artery is always a danger.
- Wound infection occurs surprisingly infrequently given the medical condition of these patients, prolonged ICU and hospital admission, and associated soft tissue injury.
- Infection and wound complications occur in about 3% of all patients.
- Patients with internal degloving injuries (a Morel-Lavallée lesion), where the skin and subcutaneous fatty layer are sheared and separated from the underlying musculofascial layers, are particularly prone to severe wound complications, with dehiscence, necrosis, and slough.
- Patients who have been identified as having an internal degloving lesion in the area of operative approach should first have drainage and débridement of the lesion, and the reduction and placement of fixation should be performed through an alternate approach.
- Neurologic injury from manipulation of fracture fragments or placement of SI screws is also a possibility.
- Careful attention to the radiologic landmarks and clear appropriate imaging should allow the surgeon to avoid these iatrogenic complications, although even smooth, gentle reductions of widely displaced fractures and dislocations can result in neuropraxic injury to the nerve roots and postoperative deficits.
- Patients need to be informed of this risk preoperatively.
- The risk of misplaced SI screws varies widely with surgeon and individual experience.
- Loss of reduction and failure of fixation can occur in very comminuted and unstable fracture-dislocations, particularly in patients with poor bone quality.
- These situations should be recognized preoperatively and intraoperatively, and the appropriate supplemental fixation (additional SI screws or spinal pelvic fixation constructs) should be applied.
- Nonunion of sacral fractures and SI dislocations is rare and not reported specifically in the literature.
- Rigidly stabilizing a sacral fracture with a residual gap predisposes to malunion and nonunion.
- Some patients with SI dislocations continue to have chronic SI joint pain, requiring SI joint fusion.

REFERENCES

DEFINITION

A posterior wall fracture is one of the elementary fracture types as described by Letournel.\(^6\) It is a fracture of the posterior rim of the socket portion of the ball-and-socket joint of the hip (FIG 1).

The disruption separates a segment of articular surface that involves varying amounts of the bony posterior wall of the acetabulum. It can exist as one single fragment or as several comminuted pieces.

The wall fracture can exist alone or as part of an associated acetabular fracture.

By definition, the posterior column, and therefore the iliosischial line, remains intact, despite varying amounts of retroacetabular surface disruption.

ANATOMY

The hip is a constrained ball-and-socket joint composed of the femoral head as the ball and the acetabulum as the socket.

The capsule surrounding the joint extends from the bony acetabular rim to the intertrochanteric line anteriorly and to the femoral neck posteriorly. It is thickened in specific areas, creating ligaments.

Anteriorly, the iliofemoral Y ligament exists as two bands. The inferior capsule is supported by the pubofemoral ligament and the posterior capsule is strengthened by the ischiofemoral ligament.

The acetabular labrum is a fibrocartilaginous structure attached to the bony rim, deepening the socket and making the joint more stable. It adds an additional 10% of coverage to the femoral head.

FIG 1 • AP (A) and Judet (B,C) radiographs of a posterior wall fracture. The posterior wall fracture fragment is outlined.
The acetabulum is composed of two columns, two walls, and the roof within the pelvis. The anterior and posterior columns form an inverted Y and are attached to the sacrum via the sacral buttress. The articular surface of the joint sits on the anterior and posterior walls and the roof, which is located within the arms of the Y.

- The anatomic roof is located between the anterior inferior iliac spine and the ilio-ischial notch of the acetabular margin.
- The weight-bearing dome, as determined by 45-degree roof arc measurements on anteroposterior (AP) and Judet radiographs, is the most important articular portion of the acetabulum. This functional aspect of the acetabulum includes the excursions of all resultant force vectors during normal daily activities.
- Two additional segments should also be considered separately.
  - The posterosuperior segment is the bridge between the roof and the posterior wall.
  - The posteroinferior segment is the lower part of the posterior wall and the posterior horn of the cartilage.
- Due to the large area of muscular attachments, the blood supply to the acetabulum is vast. Small arteries start peripherally and flow centrally, parallel to each other.
  - The largest nutrient foramina on the internal aspect of the ilium is reliably located 1 cm lateral to the sacroiliac joint and 1 cm above the iliopectineal line. It is fed by a branch of the iliolumbar artery.
  - A branch of the superior gluteal artery feeds the largest nutrient foramina on the external surface in the center of the iliac wing, just anterior to the anterior gluteal line.
  - The obturator artery supplies foramina in front of the sciatic notch just below the iliopectineal line and in the roof of the obturator canal. The body of the pubis is also supplied by the obturator artery. A branch of this artery, the acetabular branch, feeds the cotyloid fossa via a number of small perforators.
  - A complete vascular circle supplies multiple nutrient vessels around the periphery of the acetabulum. The artery of the roof of the acetabulum (from the superior gluteal artery), the obturator artery, and the inferior gluteal artery are main contributors.
  - The iliac crest, from the anterior inferior iliac spine posteriorly to the auricular articular surface of the sacroiliac joint, is supplied by branches of the external anterior iliac artery, branches of the fourth lumbar artery, and branches of the iliolumbar artery.
  - The sciatic buttress receives its blood supply from multiple branches of the superior gluteal artery.

**PATHOGENESIS**

- Acetabular fractures occur when a force is transmitted from the femur, through the femoral head, to the acetabulum. The specific pattern of the fracture is determined by the position of the hip at the time of injury and the magnitude of the force of the trauma.
- A common mechanism of injury of posterior wall fractures and fracture-dislocations is a motor vehicle crash in which the unrestrained patient is sitting with a flexed knee and the knee strikes the dashboard, creating an axial load along the length of the femur, loading the posterior aspect of the acetabulum.
- With a posterior wall fracture or fracture-dislocation, one of two possibilities exists for the capsule.
  - The capsule can rupture and allow the head to dislocate. In this scenario, varying sizes of wall fragments and labral injury can exist.
  - Alternatively, the capsule can remain intact to the wall fragment and to the femur, with all of the displacement (or even the dislocation) occurring through the fracture site.
- The size of the posterior wall fragment and the integrity of the capsule and the labrum play a role in hip stability. Despite attempts to quantitate fragment size to define operative indications, stress examination remains the only method to predict instability.
- When the capsule remains intact and the head dislocates, the fracture edges often fragment. This creates osteochondral fragments, which can lead to impaction or incarceration of the pieces upon reduction of the femoral head.
NATURAL HISTORY
- The goal of the treatment of acetabular fractures is to achieve a stable, congruent hip joint with an anatomically reduced articular surface. Anatomic reduction and stabilization will decrease the incidence of posttraumatic arthritis.8
- Although fractures of the posterior wall are common, representing 24% of Letournel’s initial series, they are frequently reported as having poor results, with 10% to 30% of patients developing post-traumatic arthritis within 1 year.
- Nonoperative treatment is unsuccessful, and Epstein3 has documented that 88% of patients treated with closed reduction alone had unsatisfactory long-term results.
- Roof arc and subchondral arc measurements do not apply to typical posterior wall fractures; however, the size of the posterior wall fragment may play a role.
- Multiple authors have attempted to define the size of the fragment that will predict instability.
  - In cadaveric studies, fragments that include greater than 50% of the wall were always unstable, while those less than 20% were stable.5,16
  - A clinical study revealed that acetabuli with less than 34% of the posterior wall intact were unstable and those with greater than 55% intact were stable.2
  - Dynamic stress examination that uses fluoroscopy to assist with the detection of suble subluxation can define a stable or unstable joint without depending on fragment size measurements.14

PATIENT HISTORY AND PHYSICAL FINDINGS
- Acetabular fractures are often the result of high-energy trauma, and therefore other associated injuries must be sought.
- Hemorrhage and hemodynamic instability are rarely associated with isolated fractures of the posterior wall; however, the superior gluteal artery and vein may be lacerated when fractures extend to the greater sciatic notch.
- Patients will frequently present with hip or groin pain and a shortened lower extremity due to the posterior, superior dislocation of the femoral head.
- Soft tissue injuries around the pelvis are uncommon because the mechanism of injury is indirect. Nonetheless, the skin overlying the hip and pelvis of any pelvic or acetabular fracture should be carefully evaluated for any subcutaneous fluctuance, ecchymosis, or cutaneous anesthesia.
  - The Morel-Lavallée lesion, a subcutaneous degloving injury, although a closed injury, is culture positive in up to 40% of cases.4 Initial débridement of these lesions as well as a delay in internal fixation is recommended by some authors.
  - Soft tissue injuries at the knee are more common and often missed. Ligamentous or chondral injuries are often discovered on secondary survey, but only if they are considered and a careful and thorough examination is performed.
  - The incidence of damage to the femoral head is unknown as the head is not routinely dislocated during fixation of the acetabular fracture for complete evaluation. However, it is not surprising when associated femoral head fractures or chondral lesions are noted, as the large amount of force needed to cause the acetabular fracture is transmitted via the femoral head.
  - Careful neurologic examination at the time of injury reveals deficits in up to 30% of cases. The peroneal division of the sciatic nerve is the most commonly seen nerve injury, especially when the femoral head is dislocated posteriorly.
  - Other ipsilateral extremity injuries often discovered include fractures of the femur, tibia, and foot.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The diagnosis and classification of an acetabular fracture is made from the initial trauma AP radiograph.
  - Two 45-degree oblique radiographs (Judet views) must be obtained also to aid in classification and treatment planning.
  - Completing the five views of the pelvis series with pelvic inlet and outlet views allows potential injuries to the pelvic ring to be evaluated.
  - A CT scan of the pelvis will assist in defining displacement, intra-articular fragments, marginal articular impaction, and associated femoral head injuries.
  - The size of the posterior wall fragment can also be determined more accurately using a CT scan, which is optimally obtained after the initial reduction.
  - The size and number of incarcerated fragments can be more precisely determined with a CT scan. Preoperative planning allows determination of the size and number of free fragments that must be removed from the joint, as well as the location of any impaction that must be elevated.

DIFFERENTIAL DIAGNOSIS
- Posterior hip dislocation
- Associated acetabular fracture
  - Associated transverse and posterior wall fracture
  - Associated posterior column and posterior wall fracture
  - Associated T-shaped fracture
  - Associated both-column fracture
  - Pelvic fracture
  - Femoral head fracture
  - Proximal femur fracture

NONOPERATIVE MANAGEMENT
- Nondisplaced, stable fractures with a congruent joint can be treated with protected, footflat weight-bearing restrictions if no instability is evident on fluoroscopic-assisted stress examination.14
- Posterior wall fractures that present dislocated should be considered a surgical emergency.
  - A prompt closed reduction with satisfactory general anesthesia is recommended.
  - The surgeon should check the femoral neck before reduction.
  - Once reduced, the joint should be evaluated fluoroscopically in both the AP and obturator oblique views for stability: the joint should be axially loaded with the hip in flexion and in flexion plus adduction.14 Only if the joint is stable (nonsubluxated) is nonoperative management sufficient.

SURGICAL MANAGEMENT
- Surgical management of acetabular fractures is technically demanding. The goal of surgery is to obtain an anatomic reduction of the joint surface and to create a congruent and stable hip joint while avoiding complications.
Other factors that play a role in surgical management include surgeon experience and the timing of operative intervention.

Letournel described his learning curve in 4-year intervals. He also reported reduced ability to achieve anatomic reduction when fractures are operated on more than 21 days after injury.

Unlike most conditions in orthopedic surgery, all displaced fractures of the acetabulum, which include marginal impaction, are indicated for surgery unless specific criteria for nonoperative management are met. These include:

A congruent hip joint on AP and Judet radiographs and on CT scan
An intact weight-bearing surface, as defined by roof arc measurements and subchondral arc measurements on CT scan
At least 50% of the posterior wall intact on CT scan
A stable joint, including on a dynamic stress examination
Patient factors must also be considered.

Age, bone quality, comorbidities, preinjury functional status, type of employment, and personal expectations all must factor into the decision-making process.

Preoperative Planning

Open reduction and internal fixation of a posterior wall fracture is based upon evaluation of the AP pelvic and Judet view radiographs and the CT scan.

The surgeon should closely evaluate the films for a transverse component, which may be overlooked on initial viewing.

The identification of marginal impaction necessitates elevating the articular cartilage and packing behind it with some form of bone graft or bone void filler to reconstruct the joint surface successfully (see Fig 2).

Careful review of the CT scan will allow identification and quantification of the number of intra-articular fragments that exist to ensure that all foreign bodies are removed from the joint upon exploration.

Positioning

Most acetabular surgeons position the patient prone on a fracture table (Fig 3).

The affected side is suspended using a distal femoral traction pin.

The peroneal post must be appropriately padded to prevent pudendal nerve palsy.

The affected leg is placed in traction, with the hip in extension and the knee flexed to at least 80 degrees; the foot is well padded and secured in a fracture table boot in the resting position. Sequential compression devices are applied to both lower extremities.

Traction is positioned to pull in line, neutral abduction–adduction, neutral internal/external rotation, with the table’s arm holding the foot free enough to allow internal and external rotation intraoperatively.

The contralateral leg is in extension in a fracture table boot with the foot well padded and in neutral position.

Pads are placed to support both thighs.

Chest pads are positioned to allow adequate room for the abdomen and breasts, and for chest excursion.

Arms are abducted to 90 degrees at the shoulders and 90 degrees at the elbows.

Once positioning is completed, PA and oblique views are obtained with the C-arm before draping or preparation to ensure that the hip is reduced and that the necessary images can be obtained.

The obturator oblique view can be obtained by rotating the C-arm 45 degrees toward a lateral view.

Pushing upward on the anterior superior iliac spine can assist with the last 15 degrees of rotation to obtain an iliac oblique view, an image that most C-arms cannot otherwise obtain.

Approach

The posterior wall of the acetabulum is accessed via the Kocher-Langenbeck approach.

KOCHER-LANGENBECK APPROACH

Incision and Dissection

The incision is based on two limbs (Tech Fig 1A).

One starts at the posterior tip of the greater trochanter and extends distally along the posterior aspect of the femoral shaft, distal to the trochanter and the gluteal crease, which serves as an external landmark for the gluteus maximus tendon.

The proximal limb extends about 45 degrees toward a spot 1 cm cephalad to the posterior superior iliac spine. The length of this limb depends on the amount of posterior column that must be accessed.

The skin and subcutaneous tissue are divided down to the fascia lata and the gluteal aponeurotic fascia.

Once identified, the tensor fascia lata and iliobibial band are sharply divided longitudinally in line with the underlying femoral shaft (Tech Fig 1B).

To open the proximal limb, the surgeon sharply divides the gluteal aponeurosis and then gently splits the gluteus maximus muscle via finger dissection.
The surgeon must watch for crossing vessels and cauterize them before they are torn.

The nerves that innervate the proximal third of the gluteus maximus will cross in this area, about halfway between the greater trochanter and the posterior superior iliac spine. The surgeon should stop splitting at the first nerve trunk to prevent postoperative palsy.

The Charnley retractor is helpful for holding the fascia away from the operative field. The surgeon must take care not to insert too deeply to prevent iatrogenic injury to the sciatic nerve.

The bursa over the trochanter is often hemorrhagic from the injury and can be resected at this time if it is large and hindering visualization (TECH FIG 1C).

Protecting the Sciatic Nerve

The sciatic nerve is identified. This can be difficult owing to the conditions of the traumatized tissues; often it will be easiest to identify the nerve in an area of healthy tissue, such as at the level of the quadratus femoris.

If overall visualization is inadequate at this point, the gluteus maximus tendon can be divided at its insertion on the femur. A cuff of tissue is left on the femur so an adequate repair can later be performed.

With the posterior aspect of the gluteus medius tendon retracted anteriorly, the piriformis tendon can be identified (TECH FIG 2A).

It can be helpful to internally rotate the leg to put the short external rotators and the piriformis on stretch to assist with identification.

In some cases the short external rotators have been avulsed by the dislocation.

It is easier to palpate the edges of the piriformis tendon with a finger and then pass a finger behind the tendon to better isolate it.

The surgeon confirms that the correct muscle has been identified by following its path backward and toward the greater sciatic notch.

Once isolated, the tendon is tagged and divided at its attachment to the femur (TECH FIG 2B). This tag suture is used to retract the muscle posteriorly (TECH FIG 2C).

With the piriformis retracted, the sciatic nerve should now be easily visible, lying over the short external rotators. The surgeon visually examines the sciatic nerve for any contusion or laceration.

Next, the surgeon identifies the tendon composed of the superior and inferior gemelli and the obturator internus.

Another tag suture is passed through this tendon, and it is released from the femur.

Since the piriformis lies superficial to the sciatic nerve, it will not retract or protect the nerve.

In contrast, the gemelli and the obturator internus can be used to effectively protect and retract the sciatic nerve posteriorly (TECH FIG 2D).

By pulling upward on this tag stitch–tendon, the surgeon can pass a finger into both the greater and lesser sciatic notches, beneath the muscle, and therefore the nerve, making a path.

A sciatic nerve retractor can then be placed along this path, into either notch. (Care should be exercised if a retractor must be placed into the greater sciatic notch due to the presence of the superior gluteal neurovascular bundle.)

By continuously checking that the external rotators are above the retractor, the surgeon can ensure that the sciatic nerve is protected. In addition to protecting the nerve, this helps to retract the soft tissues and provides excellent visualization of the retroacetabular surface.

The posterior hip capsule, the fracture line, and the posterior wall fragment are now within the surgical field (TECH FIG 2E).
With the retroacetabular surface now exposed, the fracture site and the joint must be débrided and prepared.

- By removing any residual hematoma from the field, the posterior wall fragment and the posterior column will become easily visible.
- The posterior column is inspected carefully for any nondisplaced transverse fracture line. It is better to recognize this early than to displace it later.
- The surgeon “books open” the fracture site by flipping the wall piece out into the wound.
- The posterior wall piece will typically remain attached by the capsule and some periosteum. The surgeon strips away from the wall any periosteum that may be preventing its mobilization, taking care not to injure the labral attachments. The surgeon must be sure to peel all the periosteum off the fracture edges. Direct visualization of interdigitation at the fracture site is vital in judging anatomic reduction, and the rate of nonunion is low after reduction and fixation of acetabular fractures.\(^8\)
- It is often necessary to sharply dissect the overlying gluteus minimus muscle from the posterior wall to allow mobilization.
- The femoral head will be easily visualized once the wall is mobilized and the interior of the hip joint is inspected.
- Any damage to the femoral head is noted.
- Intra-articular fragments can be removed and the joint can be irrigated to remove any other debris.
- With the fracture table used to pull traction, the joint can be distracted, which will assist with joint débridement. If the fracture table allows such movement, the hip can be flexed to assist with fragment removal.
- The intact segment must be prepared in a similar fashion.
The surgeon strips any additional periosteum and soft tissue that remains attached to the intact retroacetabular surface at the fracture edge. Again, this area will later be inspected for fracture line interdigitation.

- Any soft tissue is elevated from the top of the ischium. This will prepare the ischium to receive the reconstruction plate.
- The soft tissues superolateral to the acetabulum, on the outer table of the ilium, must be elevated in preparation to receive the proximal aspect of the plate. In this area, it is often necessary to elevate the overlying gluteus minimus muscle.

- It is safe to pass an elevator under the abductor muscles, staying on bone, down toward the iliac crest at the level of the anterior superior iliac spine. A spiked Hohmann retractor inserted in this path can also assist with retraction and visualization.

- With the fracture bed, the joint, the wall fragment, and the intact segment débrided, fracture reduction is the next step.

### FRACTURE REDUCTION

#### Reduction of Marginal Impaction

- Careful dissection of the posterior wall fragments and the intact portion of the pelvis is necessary for an accurate reduction.
- Preoperative review of all the radiographic images will normally identify any marginal impaction, which must be reduced.
- When the femoral head is sitting in the acetabulum, the areas of impaction can be reduced to the head.
- An osteotome is placed deep to the depressed subchondral bone. Gentle malting allows the osteotome beneath the impacted bone. By manipulating the bone and its overlying cartilage, the articular surface is reduced to the femoral head with its intact cartilage.
- Once reduced, there will be an empty space deep to the subchondral bone where the osteotome entered and the original bone collapsed. This area is packed with an osteoconductive bone void filler that can provide structure and prevent recollapse. Options include autogenous cancellous bone, allograft cancellous bone chips, and calcium sulfate bone graft substitute.
- As in other areas of the body, overreduction is better than underreduction, as often there is settling.
- Once the fracture bed has been meticulously débrided of fracture hematoma and soft tissue, interdigitation of the posterior wall to the remaining intact retroacetabular surface can be visualized.

#### Reducing the Posterior Wall Fragment

- With the marginal impaction reduced, attention is turned to reducing the posterior wall fragment into its bed in the intact acetabulum.

### INTERNAL FIXATION

#### Provisional Fixation

- Once the posterior wall pieces are reduced, provisional fixation to hold the fragment in place can make the overall procedure easier.
- Options for provisional fixation include either interfragmentary lag screws (2.7 or 3.5 mm) or Kirschner wires.
- By using a ball spike pusher, the fracture fragment is stabilized within its bed, and a Kirschner wire or a lag screw can be placed to hold the reduction.

- We prefer to use 2.7-mm lag screws. With these screws, the heads sit flush with the bony cortex and do not interfere with the subsequent placement of the definitive fixation.
- An alternative to a lag screw is the use of one or multiple Kirschner wires. If Kirschner wires are used, the reconstruction plate can be placed around the wires without difficulty, and subsequent removal is easy.
- Occasionally, when the posterior wall piece is small or comminuted, lag screws and Kirschner wires may not be
possible. A spring plate can be used (similar to when preventing medial wall “kick-up”).

- The end hole of a one-third tubular plate is cut into a V, creating tines. The plate is bent so the tines can effect a reduction. This plate can be used as provisional fixation to hold a small wall fragment in place or as a spring plate to prevent the medial aspect of a large wall fragment from “kicking up.”
- The tines and a portion of the plate are placed over the wall fragment. The fracture edge is spanned with the remaining plate. Either of the remaining holes of the plate can be used for screw placement, depending on the size of the wall being stabilized.
- The plate is positioned so it is possible to drill outside of the joint. Once secured, this spring plate will prevent the wall piece (if small) or the medial fracture edge (if the wall piece is large) from “kicking up” or displacing.

Reconstruction Plate Stabilization

- Now that the wall piece is reduced, it is definitively stabilized with a 3.5-mm pelvic reconstruction plate (TECH FIG 3).
- Most commonly, a slightly underbent, contoured eight-hole plate is used. It is fashioned to sit at the edge of the posterior wall, from the top of the ischial tuberosity to the bone posterior to the anterior inferior iliac spine.
- By using a finger or a Kirschner wire to feel the edge of the wall and the labrum, the surgeon can ensure that there is no portion of the plate resting on the labrum or in the joint. Placement in this location provides the greatest biomechanical advantage in buttressing the wall.
- It is not unusual for the reconstruction plate to sit on top of the heads of the lag screws or rest over the tines of the spring plate.
- With the plate adequately contoured and positioned, it is initially fixed to the pelvis at the level of the ischial tuberosity.

The surgeon drills into screw hole no. 2 from the distal aspect of the plate, which should be resting within the recess at the top of the ischial tuberosity. The surgeon aims distally and medially, into the proximal portion of the ischium. There will be good bone in this location.

Next, the plate position is checked again, at the edge of the wall but not impinging on the labrum, and then a ball spike pusher is placed into screw hole no. 8.

Since the plate is underbent, use of a ball spike pusher and the first proximal screw, placed in screw hole no. 7, will compress the plate to the posterior wall, further enhancing reduction, fixation, and stability of the posterior wall fragment.

The surgeon must take care not to violate the joint or the femoral head while drilling. In most patients, screw holes no. 7 and no. 8 are proximal to the joint even when drilling “straight” across.

The plate will now be holding the reduction, so if any Kirschner wires were used they can be removed.

The surgeon should note whether the medial aspect of the fracture fragment springs up with removal of the Kirschner wire. If it does, further fixation will be required in addition to the primary reconstruction plate.

This is an excellent time to obtain C-arm images to evaluate the reduction and to ensure that the screws have been placed extra-articularly.

One or two additional screws should be placed in the proximal end of the plate, and at least one more screw needs to be inserted into the distal part of the plate, at the most distal hole.

The most distal screw can be placed into the ischium, toward the tuberosity, where one should find great bony purchase.

Checking the Fixation

Once the final screws are placed, the surgeon evaluates the retroacetabular surface, ensuring that the medial aspect of the fracture piece has not “kicked up.”

If the medial wall kicks up, it must be further stabilized.

- A lag screw can be used in the same way as previously described.
- A three-hole one-third tubular plate spring plate is another option, as described.
- Once the medial aspect of the wall is reduced and stabilized, the smooth convexity of the retroacetabular surface should once again be restored.
- Any traction that has been applied to the extremity is removed.
- Final C-arm images are obtained to be sure that the joint is reduced and congruent and that all screws are out of the joint.
- The proximal screws are best seen with an obturator oblique view.
- The distal screws are best confirmed as extra-articular with the iliac oblique view.

TECH FIG 3 • The surgeon reduces the posterior wall piece in the fracture bed and fixes it with a buttress plate placed along the edge of the wall.
WOUND CLOSURE

- The wound is copiously irrigated.
- The surgeon checks the integrity and condition of the sciatic nerve one final time.
- A Hemovac drain is placed on the bone, along the posterior aspect of the posterior wall. A long path will help prevent inadvertent pullout of the drain and will allow hematoma to drain over a long distance.
- The first stage of closure is to reattach the piriformis and the external rotators. This can be accomplished in several different ways, including drill holes into the greater trochanter or suturing to the gluteus medius tendon. The author prefers to suture to the tendon, a site shorter than the original insertion site, to decrease the risk of pullout or failure of the repair.
- If the gluteus maximus tendon was released, it is repaired next. Typically, the tendon edges are easily visualized and sutured to each other.
- Any injured or devitalized muscle should be further débrided to decrease the risk of heterotopic ossification.
- Next, the fascia lata is identified and closed watertight.
- Routine soft tissue closure is performed. We prefer to decrease dead space, and therefore areas for hematoma to collect, with a layered closure, when possible, between the fascia lata and the skin.
- We prefer to obtain an AP pelvis radiograph with the patient supine on the regular hospital bed to inspect the reduction, the fixation, and the joint before extubation (TECH FIG 4).

PEARLS AND PITFALLS

Table and positioning
- Using a fracture table, prone positioning, and distal femoral skeletal traction reduces the risk of injuring the sciatic nerve. The hip is extended and the knee flexed to at least 80 degrees in the prone position on the table at all times, allowing the surgeon to concentrate on the procedure. Freedom is allowed in the internal–external rotation plane during the procedure to aid in soft tissue identification and manipulation and to allow differentiation between the femoral head and the edge of the posterior wall.

Internal fixation
- The reconstruction plate is placed at the lateral edge of the posterior wall to gain maximum buttressing capability. A Kirschner wire is used to feel the edge of the wall and the beginning of the labrum to clearly define location if unable to visualize with certainty. The plate is underbent to assist with the reduction.

Superior posterior wall fractures
- These fractures should be stabilized with a superior antiglide plate in addition to the traditional buttress plate.

Imaging
- Intraoperative C-arms often rotate to only 30 degrees “over the top.” To obtain an adequate iliac oblique image, the surgeon can push up on the anterior superior iliac spine, which will further rotate the pelvis and provide a more familiar radiographic image. The surgeon must be certain that all screws are out of the joint! With a convex joint, if the screw is completely out on one image, it is located outside of the joint.

Transverse fracture
- The surgeon must look for it!

Medial wall kick-up
- Often the medial aspect of the posterior wall piece will “kick up” when the plate along the edge of the wall is secured. To prevent this, the surgeon must first look for it and recognize it. Then, a three-hole one-third tubular plate, with one distal hole cut into a V to act as a hook (or a tubular 2.7 minifragment plate), can be placed along this medial aspect of the fracture. One or two screws can secure this plate, which will function as a spring plate and prevent the medial wall from kicking up. This will help restore the smooth convexity of the retroacetabular surface.
POSTOPERATIVE CARE

- A drain is maintained until drainage measures less than 30 cc in a 24-hour period.
- Antibiotics are prophylactically used until 24 hours after the drain is discontinued or until the wound is completely free of any drainage.
- Often hip wounds will have serous drainage for several days postoperatively. It is the author’s opinion that this signifies that the wound is not sealed and therefore the patient should continue to receive prophylactic antibiotics.
- Indomethacin 25 mg is given orally three times a day to prevent heterotopic ossification.
- Chemical deep venous thrombosis prophylaxis is given at the surgeon’s discretion, plus sequential compression boots for mechanical prophylaxis.
- Physical therapy restrictions
  - No active range of motion at the hip
  - Passive range of motion only; this is easily accomplished with use of a continuous passive motion (CPM) machine.
  - Any necessary flexion limit will be determined by intraoperative evaluation.
- Footflat weight bearing for 3 months is instituted immediately and patients are allowed to get out of bed the next day, once they understand their limitations.
- This weight-bearing restriction (about 30 pounds) unloads the weight of the extremity from the hip joint.
- By choosing footflat weight bearing and no active muscle contraction, the joint reaction forces of the hip joint are decreased to attempt to further protect the internal fixation and cartilage during the reparative and healing process.
- At the 3-month mark, with evidence of callus on the radiographs, weight bearing will be advanced to partial weight bearing, with the patient and the physical therapist advancing further as tolerated.
- Strengthening and gait training will begin at this time, with special concentration on the hip abductors.

OUTCOMES

- The outcome of an acetabular fracture after surgical intervention correlates with the quality of reduction and avoidance of complications.
- Although regarded as the simplest type of acetabular fracture, most posterior wall fractures are either comminuted or have marginal impaction, making anatomic reduction difficult and clinical outcomes worse than for most more complex, associated types of acetabular fractures.\textsuperscript{1,13}
- Letournel reported only a 93.7% perfect reduction rate for posterior wall fractures and an 82% good to excellent clinical outcome.\textsuperscript{6}
- Matta reported 100% anatomic reduction of posterior wall fractures in his series but only 68% good to excellent clinical outcome.\textsuperscript{8} Similarly, Moed et al had 97% perfect reductions and 89% good to excellent clinical outcomes for their series.\textsuperscript{12}

COMPLICATIONS

- Posttraumatic osteoarthritis was reported in 17% (97 of 569) of Letournel and Judet’s patients operated on within 3 weeks of injury with at least 1 year of follow-up.\textsuperscript{6} It occurred in 10.2% (43 of 418) of hips after perfect reductions and in 35.7% (54 of 151) of hips after imperfect reductions. The incidence of osteoarthritis for posterior wall fractures was 22.7% (22 of 97). It occurred in 16% (19 of 119) patients with perfect reductions. The rate after perfect reductions is higher compared to perfect reductions for all types of acetabular fractures (16% versus 10.2% respectively).
- Matta reported a 32% (7 of 22) clinical failure rate despite perfect reduction of posterior wall fractures, which was higher than for any other fracture pattern in his series.\textsuperscript{8}
- Infection after acetabular surgery is reported in about 2% to 5% of patients.\textsuperscript{6,8,9} It can be intra-articular or extra-articular, depending on the approach used. The presence of a soft tissue injury, such as a Morel-Lavallée, can increase the risk of infection.\textsuperscript{4,6}
- Heterotopic ossification occurs after use of the extended iliofemoral approach, the Kocher-Langenbeck approach, or the ilioinguinal approach when it is combined with elevation of the external fossa. Letournel and Judet reported it in 20% (41 of 208) of operatively treated posterior wall fractures.\textsuperscript{6} They also reported a decrease from 24.6% (123 of 499) in all cases via all approaches before treatment to prevent formation to 10.2% (5 of 49) in patients receiving indomethacin for prophylaxis to 0% (0 of 29) in patients receiving both indomethacin and radiation therapy.
- Indomethacin is generally considered safe and effective, although a randomized trial has questioned its utility in prevention.\textsuperscript{10}
- The unknown long-term complications associated with radiation therapy, however, make it generally not recommended for isolated posterior wall fractures in young, healthy patients.
- Avascular necrosis of the femoral head must not be confused with rapid mechanical wear or deterioration due to osteochondral injury. Epstein reported a rate of 5.3% in operatively treated posterior wall fractures.\textsuperscript{3} Letournel and Judet reported a 7.5% incidence after posterior dislocation (17 of 227) and a total of 22 of 569 (3.1%) fractures operated on within the first 3 weeks after injury.\textsuperscript{6}
- The rate of iatrogenic nerve injury, typically the sciatic nerve, is reported to be about 2% (range 2% to 18%) in the hands of experienced surgeons.\textsuperscript{6,9,11}

REFERENCES

DEFINITION
- Fractures of the femoral head are rare, and occur almost exclusively with associated high-energy hip dislocations, where they may be seen in 5% to 15% of cases.
- Associated injuries to the femur, acetabulum, or acetabular labrum can affect treatment options.

ANATOMY
- The spherical femoral head is almost completely covered by articular cartilage, which often is damaged during the hip dislocation.
- Blood is primarily supplied to the superior dome of the femoral head by the medial femoral circumflex artery, which travels around the posterior aspect of the proximal femur, traveling deep to the quadratus femoris and penetrating the joint capsule just inferior to the piriformis tendon (FIG 1).
  - Additional vascular support is supplied by the lateral femoral circumflex artery and the foveal artery within the ligamentum teres.
  - The anterior half of the femoral neck is devoid of vascular structures. Therefore, anterior surgical approaches to the hip joint do not compromise the vascular supply of the femoral head.
- The acetabular labrum increases the coverage of the femoral head, but may be damaged during hip dislocation.

PATHOGENESIS
- Both the position of the leg at the time of impact and the patient’s hip anatomy have been shown to play a role in the etiology of hip fracture-dislocations.
- Posterior dislocations, the most common type, occur when the hip is in a flexed, adducted, and internally rotated position. Decreased femoral anteverision leads to reduced femoral head coverage by the acetabulum and increases the risk of hip dislocation.
- The fracture is a shearing injury. Injury to the articular cartilage of the femoral head is common with femoral head fractures, and posterior wall fractures also can occur with this injury.
- Anterior dislocations are less common. They occur when the hip is in an abducted and externally rotated position, which results in an impaction injury to the anterolateral femoral head (FIG 2).

NATURAL HISTORY
- In an intermediate-term follow-up study by Jacob et al.,4 despite open or closed treatment, only 40% of patients had satisfactory results after hip dislocation at an average of 4.5 years after injury. More than half of the patients had posttraumatic arthrosis.
- Osteonecrosis of the femoral head may develop in 20% of patients with femoral head fractures despite anatomic reduction.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Because of the high energy required to induce a fracture-dislocation of the hip, all patients should undergo a thorough trauma evaluation for associated injuries.
  - Airway, cardiovascular, head, and spine injuries should be stabilized emergently.
  - Narcotic pain medication usually is required.
  - Careful evaluation of the affected extremity is essential.
  - The leg often appears shortened and internally rotated or flexed and abducted after a posterior hip dislocation.
  - Suspicion for associated injuries, particularly around the knee, should remain high; such injuries can be recognized on physical examination.
  - Injury to the knee ligaments or extensor mechanism is associated with traumatic hip dislocations and should be assessed with a stability examination.
- Because sciatic nerve injuries are common, motor and sensory examination of the affected extremity is critical, with particular attention paid to strength grades (1–5) and sensation in the peroneal and tibial nerve distribution.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The hip fracture-dislocation is first evaluated on the trauma anteroposterior (AP) pelvis radiograph (FIG 3A). The goal should be to emergently reduce the hip, and further imaging should not delay such treatment excessively.
- Associated injuries such as femoral neck fractures, acetabular fractures, or pelvis fractures may require additional dedicated hip, Judet view, or pelvic inlet and outlet radiographs.

FIG 1 • The blood supply to the superior dome of the femoral head is primarily supplied by the medial femoral circumflex artery. It travels around the posterior aspect of the proximal femur, traveling deep to the quadratus femoris and penetrating the joint capsule just inferior to the piriformis tendon.
A fine-cut CT scan of the pelvis and femoral neck with coronal and sagittal reconstructions will further define the anatomy of the femoral head fracture and associated injuries (FIG 3B,C).

This should be obtained after reduction of the hip. A pre-reduction CT scan of the hip is not typically indicated.

Although MRI can be used to evaluate femoral head osteonecrosis in follow-up care, acute imaging has not been demonstrated to be prognostic of this complication.

DIFFERENTIAL DIAGNOSIS

Femoral head fractures typically are classified according to Pipkin (Table 1).

An isolated posterior wall fragment may be confused with a femoral head fracture.

NONOPERATIVE MANAGEMENT

Surgical management to reconstruct the articular surface usually is indicated.

Nonoperative management is used only in Pipkin type I fractures with small articular fragments with an associated concentric reduction of the hip.

No quality clinical studies are available to define the amount of displacement of the fragment that can be tolerated. The accepted guideline is that the fragment should be congruent with the intact femoral head.

Small impaction injuries associated with anterior dislocation also may be treated nonoperatively in many cases.

Patients managed nonoperatively should remain toe-touch weight bearing for 8 to 12 weeks. For posterior dislocations, hip flexion beyond 70 degrees should be avoided for 6 weeks to protect the posterior capsule. Pool therapy can be initiated between 6 and 8 weeks.

SURGICAL MANAGEMENT

Most patients with femoral head fractures require surgery to provide an anatomic reduction of the femoral head, remove osteochondral loose bodies, or obtain a concentric reduction of the hip joint. Loose body removal can delay the onset of arthrosis.
Large, displaced fragments should be anatomically fixed. Smaller fragments inferior to the fovea can be excised if a quality, stable reduction of the fracture fragment cannot be obtained. Hip arthroplasty is another good treatment option in elderly patients, especially with large head fragments. Femoral head fractures in this age group tend to have a large amount of associated articular cartilage damage and impaction of the bone at the fracture line, which compromises the patient’s outcome.

Although their significance is unknown, labral tears often can be evaluated and treated surgically.

Algorithm for surgical management:
- Nondisplaced fracture or small impaction injury
  - Nonoperative treatment
- Displaced fracture
  - Small: surgical excision
  - Large: surgical fixation
- Elderly patient
  - Small fragment with evidence of associated femoral head impaction: surgical excision
  - Large fragment or significant femoral head impaction: hip arthroplasty

Preoperative Planning
- If the hip is dislocated, it should be emergently reduced under general anesthesia with skeletal relaxation.
- Inadequate anesthesia during this reduction can lead to further damage to the articular surfaces of the femoral head and acetabulum as the hip is relocated.
- If the hip is reduced, the patient should be placed in 30 pounds of longitudinal skeletal traction until formal open reduction and internal fixation of the femoral head occurs. Traction will unload the femoral head and prevent ongoing third-body wear within the hip joint.
- Repeat radiographs and a post-reduction CT scan should be obtained to evaluate the hip joint.
- It is reasonable at this point to delay definitive surgery until the appropriate surgeon, anesthesiologist, and equipment are available.
- If the hip is irreducible, or there is an associated femoral neck fracture, emergent open reduction and internal fixation are required.

Positioning
- For an anterior Smith-Peterson approach, the patient is positioned supine on a radiolucent table with a hip bump and the affected leg draped free.

For a posterior Kocher-Langenbeck approach, the patient is placed prone on a radiolucent fracture table with a distal femoral traction pin and the knee flexed to 90 degrees to relieve sciatic nerve tension.

For a Ganz surgical dislocation, the patient is placed on a radiolucent table with a beanbag in the lateral decubitus position and the affected leg draped free.

Approach
- The most difficult decision is determination of the best operative approach.
- Epstein originally argued that all femoral head fractures should be approached posteriorly, because the posterior blood supply to the femoral head had already been damaged during hip dislocation. This left the anterior capsular blood supply intact.
- However, the anterior capsule and anterior femoral neck provide very little vascular supply to the femoral head. In addition, visualization of the anteriorly located femoral head fracture often is inadequate.
- This approach is best used when large femoral head fragments remain dislocated posteriorly after reduction of the hip or with an associated posterior column or posterior wall fracture.
- However, visualization of the anterior head fragment is difficult through a posterior approach, and such a fracture may be better treated with a surgical dislocation (see Techniques section).

Swiontkowski effectively demonstrated that better visualization of the femoral head was obtained for most Pipkin I and II femoral head fractures by using the distal limb of an anterior Smith-Peterson approach.

No increased incidence of osteonecrosis was seen, although a slightly higher risk of heterotopic ossification was observed.

A Smith-Peterson approach is currently the most commonly used method for fixation, and is the preferred approach for excision of the fragment.

The best visualization of the femoral head can be obtained through a surgical hip dislocation, as described by Ganz et al.

This approach safely preserves the medial circumflex arterial supply to the femoral head.

It also allows the best access to associated injuries such as posterior acetabular fractures, labral tears, osteochondral debris, or posteriorly dislocated femoral head fragments.

Surgical dislocation also provides improved access to anulate lag screw fixation perpendicular to the femoral head fracture line.

SMITH-PETERSON ANTERIOR APPROACH

Incision and Dissection
- This is the preferred approach for fragment excision.
- The patient is positioned supine on a radiolucent table with the leg draped free.
- A vertical incision is made from the anterosuperior iliac spine extending distally toward the lateral border of the patella (TECH FIG 1A).
- The sartorius and tensor fascia lata are identified (TECH FIG 1B). The fascia is incised over the medial aspect of the tensor muscle, and the medial border of the tensor muscle is followed to develop the interval between the tensor and sartorius muscles (TECH FIG 1C).
- The tensor muscle is retracted laterally and the sartorius muscle medially.
- The direct and indirect heads of the rectus femoris muscle are identified and are retracted medially (TECH FIG 1D). There is an overlying fascial layer that must be divided to be able to see this muscle. The lateral femoral circumflex vessel traverses the inferior part of the wound and marks the distal aspect of the incision.
TECH FIG 1 • A. Incision starts from the anterosuperior iliac spine extending distally toward the lateral border of the patella. B. The fascia is incised over the medial border of the tensor muscle. C. The medial border of the tensor muscle is followed to develop the interval between the tensor muscle and the sartorius muscle. D. The direct and indirect heads of the rectus femoris muscle are identified and retracted medially. E. The iliocapsularis muscle lies deep to the rectus muscle. This muscle is swept medially to expose the joint capsule.
In most patients, a residual muscle belly, the ilio-capsularis muscle, is deep to the rectus muscle (TECH FIG 1E). This muscle is swept medially, exposing the capsule.

**Capsulotomy**
- A longitudinal incision is made from the articular rim to the base of the femoral neck along the axis of the femoral neck. Anteriorly, a capsular incision is made along both the acetabular rim and the base of the femoral neck (TECH FIG 2A). Posteriorly, only a capsular incision along the articular rim is made.
- Incising the capsule posteriorly along the base of the femoral neck places the medial femoral circumflex artery at risk. The medial femoral circumflex vessel, which rests in a synovial fold on the posterolateral femoral neck, and the acetabular labrum must be protected. The anterior aspect of the femoral neck is devoid of vascular structures.
- If additional exposure is necessary, a portion of the direct head of the rectus muscle may be released.
- Blunt retractors are placed within the joint capsule to obtain good exposure of the head fracture (TECH FIG 2B).

**Fracture Reduction and Fixation**
- Reduction of fragment is facilitated by cutting the ligamentum teres.
- The fragment is excised if it is too small for internal fixation.
- A pointed reduction clamp is used to reduce the displaced fragment.
  - Many fractures have a component of impaction injury on the femoral head, so the fracture may not key in circumferentially. Circumferential visualization of the fracture is necessary to confirm that adequate reduction has been obtained.
- In some cases, anterior dislocation of the femoral head will facilitate both fracture reduction and insertion of definitive fixation.
- The fracture is fixed with recessed 3.5- or 2.7-mm lag screws or headless self-compressing screws (eg, Acutrack [Acumed LLC] or Herbert-Whipple screws [Zimmer Inc.]).
  - It is important to ascertain that the screw heads are recessed within the bone.

**Ganz Surgical Dislocation**
- The patient is in the lateral position.
- Either a direct lateral incision or a traditional posterolateral approach is used.
- The gluteus maximus is retracted posteriorly and the tensor fascia lata anteriorly.
- The interval between the gluteus minimus and the piriformis is identified, and the gluteus minimus is sharply elevated anteriorly.
- The trochanter is osteotomized, leaving a portion of the tip of the trochanter intact to protect the medial femoral circumflex vessel. The osteotomy is oriented parallel to the shaft of the femur (TECH FIG 3A).
- The gluteus minimus and medius, the trochanteric fragment, and the vastus lateralis and intermedius muscles are sharply elevated anteriorly.
- The dissection is kept superior to the piriformis muscle, because the medial femoral circumflex vessel penetrates the hip capsule at the inferior margin of the piriformis.

**TECH FIG 2**
- **A.** A capsulotomy is performed by making a longitudinal incision from the articular rim to the base of the femoral neck along the axis of the femoral neck. Anteriorly, a capsular incision is made along both the acetabular rim and the base of the femoral neck. Posteriorly, only a capsular incision is made along the articular rim. **B.** After the capsulotomy is performed, blunt retractors are placed around the femoral neck to expose the femoral head and neck.
Chapter 5 ORIF OF FEMORAL HEAD FRACTURES

TECH FIG 3 • A. The trochanteric osteotomy is made parallel to the shaft of the femur. B. Z-shaped capsulotomy. C–E. Intraoperative views following surgical dislocation of the hip. The ligamentum teres was transected to improve exposure, but the medial retinaculum was left intact. The fragment is fixed with three headless screws. Note the area of femoral head bone loss due to impaction. F,G. Posterosuperior labral tear is demonstrated. The labrum is reduced and secured with suture anchors. Surgical dislocation provides the best exposure of the acetabulum and is our preferred exposure for this fracture pattern. H. Postoperative radiograph. The trochanteric fragment is stabilized with two or three 3.5-mm cortical screws directed in a cephalad to caudad direction.

- Placing the leg in the figure 4 position with the operative-side foot on the table improves exposure of the anterior capsule.
- A Z-shaped capsulotomy is performed with the cephalad limb posterior and the caudad limb anterior (TECH FIG 3B).
- The femoral head is dislocated anteriorly.
- The femoral head fragment is reduced or excised. The labrum is assessed, and is fixed with suture anchors if it is torn (TECH FIG 3C–H).
- If an associated posterior wall fragment is present, the hip is reduced and the wall fragment repaired.
- The capsule is loosely repaired, and the trochanter is reattached with two or three 3.5-mm cortical screws.
PELVIS AND LOWER EXTREMITY TRAUMA • Section I PELVIS AND HIP

POSTOPERATIVE CARE

- Patients are given 24 hours of appropriate antibiotic prophylaxis.
- Deep venous thrombosis prophylaxis is started 24 hours postoperatively, and is used before surgery if it has been delayed more than 24 hours after injury.
- Heterotopic ossification prophylaxis using either 700 cGy of radiation or indomethacin 25 mg three times daily is considered in patients with significant damage to the gluteus minimus muscle.
- Patients are allowed 30 to 40 pounds weight bearing for 8 to 12 weeks, then progressed to full weight bearing as tolerated.
- Hip flexion is limited to 70 degrees for 6 weeks.
- Pool therapy is started once the incision is dry and the sutures are removed.
- Once weight bearing is initiated at 12 weeks, more aggressive physical therapy focusing on gait training and quadriceps and hip abductor strengthening is started.

OUTCOMES

- Because of the rarity of femoral head fracture-dislocations, no large prospective trials have compared surgical versus nonsurgical treatment methods.
- Most retrospective reviews, including those by both Epstein and Jacob, report less than 50% good or excellent results at 5 to 10 years of follow-up.
- Posttraumatic arthrosis is common following a femoral head fracture, and patients should be warned early of the poor prognosis.

COMPLICATIONS

- Posttraumatic arthrosis: >50%
- Femoral head osteonecrosis: 20%
- Neurologic injury: 10% (60% of these recover some function)
- Heterotopic ossification: 25% to 65%; higher risk with anterior approach
- Hip instability
- Deep venous thrombosis

REFERENCES

DEFINITION
- Femoral neck fractures occur in two patient populations.
  - Most commonly, they happen in older, osteopenic patients after low-energy trauma, such as falls.
  - When they occur in younger patients with normal bone, they are usually the result of high-energy trauma, such as a motor vehicle collision.
- Femoral neck fractures can be classified by several characteristics. The most important distinguishing feature in regard to treatment decisions is the degree of displacement.
  - Fractures that are nondisplaced or impacted into valgus can usually be treated with fixation in situ using percutaneous methods.
  - Displaced fractures usually require reduction and fixation or replacement.
- The location of the fracture in the femoral neck can be described as subcapital, transcervical, or basicervical (FIG 1).
  - Transcervical femoral neck fractures can be further characterized by the angle of the fracture line with respect to the perpendicular of the femoral shaft axis. This is the Pauwels classification (Table 1).
  - The importance of this feature is to recognize high-angle fractures (more vertical), which have the greater risk of displacement when treated with screws along the neck axis.

ANATOMY
- The femoral neck axis forms an angle of about 140 degrees to the femoral shaft axis. In addition, it is anteverted about 15 degrees with reference to the plane of the posterior condyles of the distal femur.

PATHOGENESIS
- Low-energy femoral neck fractures generally are a result of a fall from standing height in an osteoporotic individual.
  - This is an increasing public health problem, with projections of 512,000 total hip fractures in the United States by the year 2040.1
  - High-energy (comminuted) femoral neck fractures generally result from high-speed motor vehicle collision or falls from greater than 10 feet.
  - These patients frequently have multiple injuries, which can complicate treatment.

NATURAL HISTORY
- Nondisplaced or minimally displaced fractures that are not surgically stabilized are likely to suffer worsened displacement owing to the high mechanical forces associated with hip motion and the instability that comes from comminution of the cortical bone.
  - The intra-articular location of the femoral neck means that there is not a well-vascularized soft tissue envelope, and the fracture is exposed to synovial fluid, which contains enzymes that lyse blood clot, the required first stage in bone healing. As a result, femoral neck fracture healing is slowed.
  - In addition, the blood supply comes from tenuous retrograde blood flow.
  - Nonunion rate for untreated displaced fractures approaches 100%.
  - Nonunion of the femoral neck leads to a shortened limb, variable restriction in motion, and pain with weight bearing.
  - Fracture of the femoral neck can lead to interruption of the blood supply to the femoral head due to kinking or disruption of vessels or tamponade from hemarthrosis.
  - This results in avascular necrosis in about 15% of cases.2
  - Many surgeons believe that time to treatment is an important factor, with delay increasing the incidence. This is difficult to prove, and the time imperative probably varies from patient to patient.
  - Femoral neck fractures in the elderly are associated with about 20% 1-year mortality.4
  - About 50% of patients return to their previous level of function after surgery.3
PATIENT HISTORY AND PHYSICAL FINDINGS

- In most patients with femoral neck fracture, the history will contain a distinct traumatic episode, after which the patient could not ambulate.
- Physical findings reveal limb shortening, external rotation, and pain on attempted hip motion.
- In some patients, the onset of pain is more insidious.
  - It is usually associated with weight bearing, and it is located in the groin rather than in the buttock or trochanteric area.
  - In the case of a stress fracture, the history of increased activity over a short period of time is suggestive.
  - Night or rest pain suggests pathologic fracture or impending fracture.
- In highly osteoporotic patients with minor trauma, a history of groin pain with weight bearing may be a symptom of occult femoral neck fracture, which is a nondisplaced fracture not visible on plain radiographs.
- Physical examination should include:
  - Observation of the lower extremities with comparison of foot position in the supine patient. A shortened, externally rotated limb indicates fracture.
  - Gait observation. Groin pain on attempted weight bearing or an antalgic gait suggests occult femoral neck fracture.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard plain radiographs consist of an AP view of the pelvis and AP and frog-leg lateral films of the hip.
- An AP traction film with internal rotation can be helpful if initial films are difficult to interpret in terms of the location of injury or fracture pattern.
- If clinical suspicion is high (eg, an elderly patient who cannot ambulate because of groin pain) but plain radiographs are negative, a bone scan or MRI may be obtained for low-energy injuries.
  - The bone scan will not turn positive for 24 to 72 hours, but the MRI should be diagnostic within hours of injury.
- Some studies have suggested that any multiply injured patient with a high-energy femur fracture should have imaging of the femoral neck with a CT scan in addition to plain films to identify minimally displaced femoral neck fractures. However, the CT scan may be false negative as well, and the routine use of this modality is controversial.

DIFFERENTIAL DIAGNOSIS
- Intertrochanteric, pertrochanteric, or subtrochanteric fracture
- Anterior pelvic ring (ramus) fracture
- Hip dislocation
- Femoral head fracture
- Pathologic lesion, including neoplasm or infection
- Arthritis
- Avascular necrosis
- Contusion
- Muscle strain

NONOPERATIVE MANAGEMENT
- Nonoperative treatment may be appropriate in patients who are nonambulators, neurologically impaired, moribund, or in extremis.
- Nonoperative treatment should initially consist of bed rest, appropriate analgesia, protection against decubitus ulcers, and appropriate medical supportive treatment.
- Buck’s traction or pillow splints may be helpful in reducing pain.
- As soon as pain control is adequate, patients should be mobilized out of bed to a chair to help prevent the complications of bed rest, such as pneumonia, aspiration, skin breakdown, and urinary tract infection.
- Some valgus impacted fractures may be treated nonoperatively, particularly if discovered after several weeks, but there is a risk of displacement of up to 46%.
- Nonoperative treatment for these patients should consist of mobilization on crutches or a walker.
- Stress fractures may be treated nonoperatively if they are caught early and are nondisplaced and if the fracture line does not extend to the tension side or superior neck.

SURGICAL MANAGEMENT
- Most patients with femoral neck fracture should be considered for surgical treatment.
- Displaced femoral neck fractures in some patient populations may be better served by hemiarthroplasty or

FIG 2 • A,B. AP and lateral model showing gentle S curve of the outline of the head and neck. This smooth contour should be present and symmetrical on superior, inferior, anterior, and posterior surfaces. C,D. Vascular supply to the femoral head. The medial and lateral femoral circumflex arteries arise from the profunda femoris and form a ring around the base of the femoral neck, which is predominantly extracapsular. From this ring, the arteries of the retinaculum of Weitbrecht ascend along the femoral neck to provide retrograde flow to the femoral head. The foveal artery arises from the obturator artery and supplies a variable but usually minor portion of the femoral head.
total hip arthroplasty, which is beyond the scope of this chapter.

- This includes elderly patients, osteoporotic patients, those with neurologic disease, patients with preexisting hip arthritis, and those with medical illnesses impairing bone healing or longevity (eg, renal failure, diabetes, malignancy, or anticonvulsant treatment).

- Nondisplaced fractures, valgus-impacted femoral neck fractures in the elderly, or stress fractures in athletes can be treated with fixation in situ through percutaneous techniques.

- Open reduction and internal fixation is the standard for high-energy injuries in younger healthy patients with good bone.

- Closed reduction of a displaced femoral neck fracture in the young patient is difficult, and one should not accept a less-than-perfect reduction to avoid an open procedure.

- The quality of the reduction is the most important surgeon-controlled factor in outcome.

Preoperative Planning

- Once the decision for operative treatment is made, preoperative planning begins with evaluation of patient-specific factors that may alter the timing or technique for fixation of the femoral neck fracture.

- In the elderly population, optimization of medical conditions is advisable, including evaluation of hydration and cardiac and pulmonary function, and management of chronic medical conditions. However, delay of surgery beyond the first 2 to 4 days increases the risk of perioperative complications and the length of stay.

- In younger patients, it is important to consider other injuries that may affect operative positioning or fixation. For example, ipsilateral lower extremity injuries at another level may affect the use of the fracture table.

- Good-quality radiographs in two planes are necessary to understand the location and orientation of the fracture. In some cases, radiographs of the contralateral side may help select an implant with the correct length, diameter, or neck–shaft angle.

- The anticipated implants should be verified present before the case. It is useful to have arthroplasty instruments and implants in the hospital in the event of unexpected findings. Fortunately, this will rarely be needed.

- Nondisplaced fractures in the subcapital or transcervical region can be treated with two or three cannulated screws, but most surgeons believe that basivascular fractures should be treated with a fixed-angle device, such as a sliding hip screw or cephalomedullary nail.

Positioning

- The patient is positioned on a fracture table with both hips extended. The contralateral leg is abducted to allow the C-arm to be positioned between the legs (Fig 3A).

- Owing to the risk of compartment syndrome, the surgeon should avoid using the “well leg holder,” which puts the contralateral leg in a hemi-lithotomy position (hip and knee flexed, elevating the leg).

- Intraoperative fluoroscopy is used, and good visualization of the hip and the fracture reduction in both AP and lateral projections should be verified before preparing the leg (Fig 3B).

- A closed reduction may sometimes be obtained by applying gentle traction and internal rotation under fluoroscopic control (Fig 3A). Vigorous and complicated reduction maneuvers are unlikely to be effective and should be avoided. If simple, gentle positioning is not successful in achieving acceptable position, open reduction should be strongly considered. The patient should be well relaxed by the anesthesia team.

- Reduction is anatomic when the normal contours of the femoral neck are re-established in both the AP and lateral projections (see Fig 2A,B), the normal neck–shaft angle and neck length are restored (as judged from a film of the contralateral hip, or AP pelvis), the relative heights of the femoral head and trochanter are symmetrical to the contralateral side, and no gaps are seen in the fracture.

- If the C-arm images are of poor quality because of patient obesity or other factors, the surgeon must not assume or hope it will be better intraoperatively. If adequate visualization to

**FIG 3**

A. Patient positioning on fracture table. Both legs are supported in the extended position in padded foot supports. The injured leg is kept in neutral abduction–adduction, while the uninjured leg is abducted to allow placement of the C-arm between the legs. The injured leg may be internally rotated to assist with reduction. B. Fracture table and C-arm positioning to obtain a lateral view of the femoral neck.
assess reduction or implant position is not achievable, open reduction under direct visualization is the prudent course.

**Approach**
- A standard lateral approach is used for percutaneous fixation of nondisplaced or valgus impacted fractures.
- If an open reduction is planned, a Smith-Peterson or Watson-Jones approach may be used according to surgeon preference to afford visualization of the anterior femoral neck.
- The Watson-Jones approach is the senior author’s preference and is described below.

**CLOSED REDUCTION AND PERCUTANEOUS FIXATION**

- The patient is positioned on the fracture table and reduction is obtained as noted above, C-arm visualization is verified, and the leg and hip is prepared and draped in a sterile fashion.
- Preoperative antibiotics are given.

**Guidewire and Screw Placement**
- Guidewires for cannulated screws are placed in line with the femoral neck axis through poke holes.
  - The wires are placed parallel, using a parallel drill guide.
  - The standard screw arrangement is an inverted triangle of three screws.
  - They should be positioned peripherally in the femoral neck with good cortical buttress, particularly against the inferior and posterior neck. Starting points below the lesser trochanter should be avoided owing to risk of subtrochanteric fracture postoperatively (TECH FIG 1A–C).
- Once the position of the wires is verified in two planes by fluoroscopy, small (1-cm) full-depth incisions are made at each guide pin, and the soft tissues are spread to the bone.
- The lateral cortex may be drilled in patients with dense bone.
- Self-drilling, self-tapping cannulated screws are placed by power over the guidewires.
- Washers should be used in the more proximal, metaphyseal locations (TECH FIG 1D,E).
- Screws should be long enough so that all screw threads are on the proximal (head) side of the fracture.

**TECH FIG 1**
- **A.** Sawbones lateral view of the proximal femur showing configuration for three parallel guidewires before placement of cannulated screws. The wire starting points form an inverted triangle. **B.** Intraoperative AP fluoroscopic view showing position and depth of the guidewires. The inferior wire runs right along the inferior cortex of the femoral neck—the “calcar” (arrow). **C.** Intraoperative lateral fluoroscopic view showing guidewire position. The posterior wire is directly adjacent to and supported by the posterior cortex of the neck. Care is necessary to ensure that the guidewire does not go outside of the neck and then re-enter the femoral head. **D,E.** Intraoperative fluoroscopic views demonstrating cannulated screw insertion over guidewires. **D.** AP view showing use of washers in this metaphyseal location. **E.** Lateral view showing parallel insertion and appropriate depth.
Arthrotomy
- Many surgeons believe that an arthrotomy should be performed to relieve pressure on the blood supply to the femoral head due to intracapsular bleeding. Some consider this to be mostly important in younger patients with minimally displaced fractures, because they reason that more widely displaced fractures have had decompression of the intracapsular hematoma by virtue of the injury. This is controversial.
  - A no.15 blade on a long handle is positioned at the inferior margin of the base of the femoral neck on the AP fluoroscopic image.
  - A small skin incision is made at this level, and the soft tissues are spread down to the joint capsule.
  - With fluoroscopic verification of position, a small capsulotomy is performed to allow drainage of the hematoma from the capsule.
  - A blunt sucker tip can be inserted through this small incision to evacuate any remaining hematoma.

OPEN REDUCTION AND INTERNAL FIXATION THROUGH THE WATSON-JONES APPROACH

The patient is positioned on the fracture table as noted above, fluoroscopic visualization is confirmed, and the leg and hip is prepared and draped in a sterile fashion.
- Circumferential proximal thigh preparation is important.
- Preoperative antibiotics are given.

Fracture Reduction
- A 4.5-mm Schanz pin should be placed in the proximal femoral shaft at the subtrochanteric level to facilitate reduction. The use of a T-handle chuck will allow easier manipulation of this pin.
- A 2.5-mm terminally threaded Kirschner wire is placed in the femoral head at the articular margin to serve as a joystick in the proximal (head) fragment. Sometimes it is necessary to use two such joysticks to accurately position the head, which, because of its spherical nature, may be difficult to position along three axes simultaneously.
- Reduction is performed under direct visualization using the Kirschner wire and Schanz pin to manipulate the fragments.
- Internal rotation of the shaft, along with external rotation and adduction (valgusization) of the head fragment, is usually required.
- Occasionally a bone hook under the medial inferior portion of the neck will help.
- The reduction is verified by keying the opposing cortical surfaces on the anterior, superior, and inferior neck together under direct visualization. A finger can be gently used to feel the surfaces and verify a smooth reduction without gaps or translation. Hard instruments should not be used for this to avoid damage to the delicate blood vessels on the neck.
- The reduction is temporarily stabilized with at least two terminally threaded 2.5-mm Kirschner wires placed from the lateral femoral cortex.
- It is verified by fluoroscopy in two planes.
- When the reduction is anatomic and temporarily stabilized, definitive fixation devices (cannulated screw guidewires, sliding hip screw, or cephalomedullary nail guide) are positioned.

Screw Placement
- Screw fixation is performed as described above for percutaneous stabilization.

Soft Tissue Dissection
- The incision is located laterally over the anterior portion of the greater trochanter.
- It curves slightly anteriorly as it extends proximal from the trochanter toward the crest for about 8 to 10 cm.
- It extends straight distally about 10 cm from the trochanter (TECH FIG 2A).
- The fascia lata is identified and incised just posterior to the tensor fascia lata muscle.
- This incision through the fascia extends the length of the skin incision (TECH FIG 2B).
- The anterior inferior edge of the gluteus minimus is identified.
- The interval between the minimus and the joint capsule is developed.
- A portion of the minimus insertion on the trochanter can be gently released to facilitate retraction with a curved blunt Hohmann retractor.
- The reflected head of the rectus femoris is identified (TECH FIG 2C) and divided (TECH FIG 2D), leaving a stump to repair.
- A Cobb elevator can be used to clean muscle fibers off the anterior capsule.
- The capsule is incised in line with the femoral neck axis (TECH FIG 2E) and then released in a T shape along the acetabular edge (TECH FIG 2F).
- Blunt Hohmann retractors can be moved inside the capsule. The surgeon must take care to be very gentle against the posterior femoral neck (TECH FIG 2G).
- The fracture should be clearly exposed.
- If necessary, the distal part of the capsule, where it inserts anteriorly at the base of the neck, can be released, converting the T arthrotomy to a lazy H (or an l).
TECH FIG 2 - A. Landmarks for Watson-Jones approach: ASIS, anterior superior iliac spine; TFL, tensor fascia lata; GT, greater trochanter; F, femur. The crosshatched line is the incision. B. Interval for Watson-Jones approach, shown here between tensor fascia lata anteriorly and gluteus maximus posteriorly, is indicated by the position of the forceps. C. The anterior surface of the hip joint capsule has been cleared off. The retractor at the top of the picture (anterior on the patient) is under the tensor fascia lata, and the retractor to the left side of the picture (cephalad) is under the leading edge of the gluteus minimus. The reflected head of the rectus femoris, attaching on the top of the joint capsule, is grasped by the forceps. D. The reflected head of the rectus femoris has been divided and tagged with suture. E. The scalpel is in position to perform arthrotomy of the anterior capsule in line with femoral neck. The sutures are in the proximal stump of the reflected head of the rectus. F. A T-capsulotomy has been performed, with the transverse arm toward the acetabulum (proximal). G. The femoral neck is exposed with the gentle use of Hohmann retractors inside the capsule.
- For high-angle transcervical fractures (Pauwels 3), a lag screw should be positioned in a more horizontal orientation, perpendicular to the fracture plane, to provide compression, which will resist the tendency for shear forces to displace the fracture.
- Alternatively, a fixed-angle implant such as a sliding hip screw or cephalomedullary nail could be used and may give better mechanical fixation in a comminuted fracture or Pauwels 3 fracture pattern.
- Reduction and implant position should be verified with the C-arm.

### Wound Closure
- Wound closure includes repair of the capsule, restoration of the reflected head of the rectus, and closure of the fascia lata.
- Layered closure of the skin and sterile dressings complete the job.
- Portable radiographs in the operating room with the patient still asleep, with the back table still sterile, are useful to avoid nasty surprises in the recovery room.

### CEPHALOMEDULLARY NAIL FIXATION
- The patient is positioned on the fracture table as noted above, fluoroscopic visualization is confirmed, and the leg and hip is prepared and draped in a sterile fashion.
  - Circumferential proximal thigh preparation is important.
  - Preoperative antibiotics are given.

#### Incision and Dissection
- A small incision, usually 3 to 4 cm long, is made several centimeters proximal to the tip of the greater trochanter to allow passage of the nail (TECH FIG 3).
- A periosteal elevator can be used to spread the gluteus medius fibers in line with the incision.
- Blunt dissection with an elevator or a finger provides access to the starting point. The tip of the greater trochanter is palpated. The tendon of the gluteus medius attaching to the trochanter can be felt and is protected.

#### Starting Point and Reaming
- Using fluoroscopy, a starting point is obtained for the nail at the medial edge of the greater trochanter for a trochanteric starting cephalomedullary nail.
  - The starting point should be just lateral to the piri-formis fossa (TECH FIG 4A).
  - Alternatively, an awl can also be used to obtain the proper starting point; this can be especially useful in obese patients.
  - An anatomic reduction of the femoral neck must be achieved before reaming.
  - If an anatomic reduction cannot be achieved by closed means, an open reduction must be performed.
  - This can be done by a Smith-Peterson or Watson-Jones approach, as described above.
  - An antirotational pin may be used to maintain reduction (TECH FIG 4B,C).

Once reduction has been obtained, the entry reamer is introduced (TECH FIG 4D).
- For a short cephalomedullary nail, the entry reamer is all that is needed before nail passage.
- If a long cephalomedullary nail is being placed, serial reaming can be performed to 1 to 1.5 cm over the desired nail diameter.

#### Proximal and Distal Interlocking
- After the nail is positioned at the correct depth, the guidewire into the femoral head is placed.
  - Multiple fluoroscopic images are needed to make sure the tip of the guidewire is placed within the center of the femoral head for nails with a single screw going into the head.
  - Newer nails with more than one screw going into the head may necessitate adjustments to this technique to allow passage of both screws (such as placing the first lag screw slightly superior to center to allow passage of the second screw inferior to center).
  - A depth gauge is used to check the length of the guidewire.
  - For rotationally unstable femoral neck fractures, an antirotational guidewire or screw can be placed to prevent rotation of the fracture with tapping (TECH FIG 5A).
  - Many nail systems allow a pin to be placed through a sheath attached to the jig, or have an antirotational bar.
  - A reamer is then used to open the outer cortex of the femur and is continued into the head under fluoroscopic guidance.
The reamer should be checked during passage to ensure the guidewire is not being driven into the pelvis and the reduction is not lost during reaming.

The lag screw is then tapped, and fluoroscopy is again used to ensure the reduction is not lost.

The lag screw is placed and fluoroscopy undertaken in multiple views to rule out penetration of the subchondral surface.

If a distal interlock is desired, it is then placed.

Most nail systems have a set screw that needs to be advanced to give rotational control to the lag screw.

If compression is desired, the set screw then needs to be loosened, usually a quarter-turn of the screwdriver, according to the recommendations of the individual nail system being used.

As above, appropriate films should be taken with the patient asleep. This may include plain films if fluoroscopy is not adequate (TECH FIG 5B, C).

Tech Fig 5 • A. Antirotational screw is placed in addition to guidewire before tapping when using a sliding hip screw or cephalomedullary nail.

B. Preoperative radiograph showing a displaced femoral neck fracture.

C. Final intraoperative AP fluoroscopic view showing anatomic reduction with antirotational screw with cephalomedullary nail.
MINIMALLY INVASIVE FIXATION WITH A SLIDING HIP SCREW

Positioning, Reduction, and Guidewire Placement

- The patient is positioned on the fracture table as noted above and in Chapter TR-8, except that we do not use a well leg holder because of risk of compartment syndrome. Occasionally, in patients with adduction contracture, the well leg cannot be abducted enough with the hip extended to allow access of the C-arm. In these cases, the well leg holder is used as described in Chapter TR-15. Fluoroscopic visualization is performed, and reduction is confirmed to be acceptable in all planes.
- In femoral neck fractures, as opposed to intertrochanteric or pertrochanteric fractures, the reduction must be verified as anatomic if one is to expect stability and healing.
- In this approach, as opposed to the technique described in Chapter TR-15, the guidewire is inserted percutaneously by poking through the skin under the guidance of fluoroscopy and with use of an appropriate angle guide (TECH FIG 6A).
- The guidewire is positioned in the center of the femoral neck and head as described in Chapter TR-15 (TECH FIG 6B).

If the fracture is rotationally unstable (transcervical, comminuted, widely displaced before reduction), an anterotational wire or screw should be placed up the neck across the fracture to prevent loss of reduction (see Tech Fig 5A).

Incision and Preparation of Bone

- An incision is made beginning at the guidewire and extending distally for 4 to 5 cm (TECH FIG 7A).
- A full-thickness skin-to-bone incision is made.
- Soft tissues are gently spread with a clamp, and an elevator is used to clear tissue from the lateral cortex distal to the pin entry site for the length of a two-hole plate.
- The guidewire is measured.
- The reamer is then set to this depth (TECH FIG 7B).
- Fluoroscopy should be checked intermittently during reaming because the guidewire can migrate into the pelvis if bound by the reamer.

Implant Placement

- The lag screw is then placed over the guidewire in standard fashion (TECH FIG 8).
- The femoral neck-shaft angle has been set by placement of the guide pin, but it can be measured intraoperatively with a guide to select the appropriate implant.
- This is usually a 135-degree side plate if placed correctly.
- The side plate is then placed over the lag screw and gently worked through the soft tissues until it is placed into...
contact with the lateral cortex. The skin is quite mobile and elastic, and with a little stretching the plate can be positioned easily.

- Final seating can be done with light blows of a mallet with the aid of a “candlestick” impaction device.
- A two-hole plate is sufficient.
- If lag screw was not placed with the key parallel to the femoral shaft, most systems allow this to be corrected by simply reapplying the T-handle screwdriver to the lag screw and turning the plate and screw as one unit until the plate fits appropriately.
- Usually only two bicortical screws are needed through the side plate into the shaft.
- As above, appropriate films should be taken with the patient asleep. This may include plain films if fluoroscopy is not adequate.

PEARLS AND PITFALLS

Imaging
- The pattern of injury must be recognized preoperatively. A traction film with internal rotation can help with this, as initial plain films are usually externally rotated and may be difficult to interpret.
- If the clinical examination is suspicious despite negative plain films, a screening MRI is indicated to rule out an occult femoral neck fracture.
- Although controversial, a CT scan of the femoral neck should be considered in all trauma patients with femur fractures.

Positioning
- Pelvic rotation: Either scissor legs with the fracture table, or the torso is leaned away from the affected side to prevent pelvic tilt.
- The patients should be draped wide, from the lower ribs to below the knee, to allow complete access to the femur if problems arise.

Reduction
- Internal rotation of the fractured-side leg holder will reduce anterior neck diastasis.
- Guidewire joysticks using 2.5-mm terminally threaded Kirschner wires and Schanz pins can be used to help obtain reduction (usually used when an open reduction is necessary).
- Reduction is facilitated by complete muscle relaxation.
- An anatomic reduction is necessary. An open approach should be used if there is any question that the reduction is not perfect.

Fixation
- The surgeon should avoid starting screws inferior to the lesser trochanter to minimize the risk of subtrochanteric femur fracture.
- Screws are positioned against the femoral neck cortex, especially inferiorly and posteriorly.
- For high-angle fractures (Pauwels type 3), the surgeon should consider using an additional horizontal screw, sliding hip screw, or cephalomedullary nail.
- If the fracture is comminuted or rotationally unstable, the surgeon should consider placing a sliding hip screw or cephalomedullary nail.
- If using a sliding hip screw or cephalomedullary nail, the tip–apex distance should be 25 mm or less, calculated by adding the distance from the center of the femoral head at the level of the subchondral bone to the tip of the screw on both the AP and lateral radiographs.

POSTOPERATIVE CARE
- In the elderly, mentally competent patient with stable fixation, weight bearing is allowed as tolerated.
- For deep vein thrombosis prophylaxis, the length and type of treatment are controversial, but some form of prophylaxis should be given at least during the patient’s hospital stay.
- A first-generation cephalosporin is given for 24 hours postoperatively.

OUTCOMES
- The 1-year mortality rate is about 20% in the elderly.
- About 50% of patients return to their previous level of function.

COMPLICATIONS
- There is a 16% rate of avascular necrosis with displaced femoral neck fractures.
There is a 33% rate of nonunion with displaced femoral neck fractures.²

REFERENCES
Fractures of the proximal femur are usually grouped into four major types reflecting differences in the anatomic and physiologic character of these regions:

- Femoral head fractures
- Intracapsular femoral neck fractures
- Pertrochanteric fractures (also referred to as intertrochanteric and peritrochanteric), which include proximal extracapsular fractures of the femoral neck region to the region along the lesser trochanter before the development of the medullary canal
- Subtrochanteric fractures

Cephalomedullary nailing is the surgical stabilization of the fracture with an intramedullary device usually inserted through the piriformis fossa, the lateral greater trochanter, or the medial greater trochanter.

- The cephalic or femoral head portion of the fixation construct is one or more screw or blade devices interlocked with the nail component of the construct.
- Cephalomedullary nails are most commonly indicated in extracapsular peritrochanteric and subtrochanteric fractures. Although there is occasional overlap of these regions, the personality of the fracture will be predominantly one of these major types.

**ANATOMY**

- The transitional anatomy from the femoral head to the subtrochanteric region affords very different fracture pathogeneses, affecting the surgical opportunity for repair.
- Intracapsular fractures of the femoral neck are critically dependent on the vascular supply from the medial femoral circumflex artery for fracture repair and maintenance of vascularity of the femoral head to avoid avascular necrosis.
- Conversely, the well-vascularized pertrochanteric region is dependent on the structural integrity of an essentially solid cancellous bone block from the triangle of Ward to the lesser trochanter, where the solid nature of the structure changes to a tubular construct with the origin of the femoral medullary canal (FIG 1A).
- Subtrochanteric fractures incur the highest stresses in the proximal femur owing to their tubular anatomy, which places high degrees of stress on the implants used for their fixation.
- The muscular attachments of the gluteus medius in the lateral aspect of the greater trochanter and the iliopsoas insertion in the lesser trochanter are key determinants in the deforming forces associated with fracture displacement and functional recovery after injury (FIG 1B).

**PATHOGENESIS**

- Fractures of the proximal femur fall into three mechanistic categories:
  - Low-energy same-level falls, predominantly in the senior population (50 to 80 years), often associated with osteoporosis and muscular atrophy
  - High-energy trauma in the 18- to 45-year age group from motor vehicle collisions and falls from greater heights, resulting in fractures with marked displacement and comminution
  - Pathologic fractures, often the first indication of a neoplastic process

**NATURAL HISTORY**

- To obtain any real hope of ambulatory recovery, surgical treatment is necessary for complete fractures, as the resulting deformity of a nonoperatively treated hip invariably results in significant shortening and varus deformity.
- Functional recovery is actually very poor despite surgical treatment of these fractures with conventional techniques in the 50- to 80-year age group.
- The American Academy of Orthopaedic Surgeons estimates a 24% mortality rate in patients older than 50 within 1 year after fracture, and only 25% of patients make a full recovery.²

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Pertinent history for a hip fracture patient focuses on the mechanism of injury for insight into the potential quality of bone available for repair and associated injuries in high-energy trauma.
- Associated injuries or premorbid diseases may coexist with the fracture diagnosis. Syncopal episodes resulting in a fall may bring attention to cardiovascular and neurologic disease states.
- A history of any tumor or malignant disease, including the last mammogram and breast examination in women older than 45 and the last prostate examination in men older than 40, may suggest an underlying pathologic etiology for the fracture.
- Drug use, either illicit or prescribed, as a confounding and contributing factor must be sought.
- Unfortunately, nursing home and institutionalized patients must be examined for potential neglect and abuse.
- The physical findings of a displaced hip fracture are shortening of the extremity, deformity of rotation compared to the contralateral extremity, and pain or crepitance with motion at the hip.
- Shortening and rotational deformity may be the result of varus deformity at the hip from associated muscular pull or telescoping of 100% displaced fragments.
- Examination should also include the Lippmann test (auscultation). Decreased tone or pitch implies fracture. Sound conduction through the pelvis and hip from the pelvis is interrupted by any discontinuity from the patella, femur, or pelvic articulations.
Swelling and discoloration with hematoma are signs of injury but are usually not acutely present.
Lacerations, Morel-Lavalle lesions, and decubitus ulcers may complicate the surgical approach.
Extracapsular proximal femur fractures extravasate blood into the surrounding tissues.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs, including an anteroposterior (AP) view of the pelvis, AP and cross-table lateral views of the affected hip, and AP and lateral radiographs, are required for diagnosis and preoperative planning.
- If a long nail implant is a consideration, AP and lateral radiographs of the affected femur to the knee are required, with special attention to femoral bow and medullary canal diameter.
- CT or MRI scans are rarely required for displaced fractures but may be useful in establishing the diagnosis in nonobvious fractures and atypical fractures in high-energy trauma patients.
- If a pathologic etiology is suspected, however, an MRI or PET scan of the body should be considered as part of the initial workup.
- Intraoperative or preoperative traction radiography or fluoroscopic C-arm views may be helpful in delineating the extent of complex fractures.
- Intraoperative length measurements with the C-arm of the normal femur may be helpful in selecting the correct nail length in complex fractures (**FIG 2**).

**DIFFERENTIAL DIAGNOSIS**
- Painful arthropathy (osteoarthritis, rheumatoid arthritis, septic)
- Established nonunion of the proximal femur
- Pathologic deformity (ie, Paget disease, fibrous dysplasia of the hip)
- Pubic rami fracture
- Acetabular fracture
- Contiguous femoral fracture
- Hip fracture-dislocation (rare)

**NONOPERATIVE MANAGEMENT**
- Nonoperative treatment is frequently the best option in non-ambulatory or chronic dementia patients with pain controllable with analgesics and rest, patients with terminal disease with less than 6 weeks of life expected, patients with unresolvable medical comorbidities that preclude surgical treatment, and patients with active infectious diseases that preclude insertion of a surgical implant.
- An exception is incomplete pertrochanteric fractures diagnosed by MRI, which have been shown to heal with nonoperative measures in selective patients.¹

**FIG 1**
- **A.** Radiographic anatomy of the proximal femoral fracture zones. Note greater trochanter and lateral wall and lesser trochanter and medial wall.
- **B.** Muscle attachments in subtrochanteric fractures accounting for the subsequent deformity of the fracture.

**FIG 2**
- Estimate of nail required from intraoperative radiograph of normal femur with nail in box.
Nonoperative management must include attentive nursing care with frequent positioning to avoid decubitus, attention to nutrition and fluid homeostasis, and adequate analgesia or narcotic pain suppression. Patients may be mobilized from bed to chair as tolerated, usually after 7 to 14 days, with careful support and elevation of the affected extremity.

Fracture callus at 3 weeks markedly decreases motion-related pain, and by 6 weeks most patients can be lifted into a wheelchair or reclining chair.

Ambulatory ability should not be anticipated after nonoperative treatment of displaced fractures.

**SURGICAL MANAGEMENT**

Surgical management, once selected, should be performed as soon as any correctable metabolic, hematologic, or organ system instabilities have been rectified. Usually this is within the first 24 to 48 hours for most patients.

The literature is inconclusive as to increased mortality after this time, but patient suffering and hospital efficiencies demand timely intervention.

**Preoperative Planning**

Standard AP pelvis and AP hip radiographs are usually obtained. Cross-table lateral and films in traction are useful if the hip fracture pattern is complex. Hip fractures are three-dimensional entities, and this is readily apparent in high-energy trauma cases. Full-length radiographs of good quality are required before surgery to evaluate the full extent of damage to the femur, to estimate the length and diameter of implant selections, and to avoid neglect of skip lesions or segmental damage to the femur.

Classifications for pertrochanteric and subtrochanteric hip fractures have not been particularly helpful in clinical situations, although increased surgical complexity is associated with unstable fracture patterns.5

- Unstable characteristics include posteromedial large separate fragmentation, basi-cervical patterns, reverse obliquity patterns, and displaced greater trochanteric or lateral wall fractures.
- The Evans, Kyle, AO/OTA, and Russell-Taylor classifications are commonly referred to in the literature.
- The Russell-Taylor classification assists in implant selection for the proximal femur by drawing attention to the high-risk attributes of the proximal femoral anatomy, particularly the absence or presence of fracture extension into the greater trochanter (lateral wall), referred to as group I (intact greater trochanteric region) and group II (fracture extension), and secondly the absence or presence of medial cortical stability in the lesser trochanteric region, referred to as type A (stable contact possible) and type B (fracture instability) (FIG 3).17
- Russell-Taylor type IA fractures are in reality high diaphyseal femoral fractures within 5 cm of the lesser trochanter and are preferentially treated with conventional interlocking nails, with the surgeon’s choice of either trochanteric or piriformis entry devices.
- Russell-Taylor type IB fractures are fractures at the diaphyseal–metaphyseal junction of the proximal femur with medial instability due to fracture comminution. The greater trochanter and lateral wall are intact, and cephalomedullary nails, either of the reconstruction nail class or gamma nail class, are indicated, with either a trochanteric or piriformis entry type of device with the respective portal.
- Russell-Taylor type IIA fractures are fractures involving the greater trochanter and lateral wall but have the possibility of restoration of medial cortical stability. Reverse obliquity patterns fall into this group. If the greater trochanter is displaced, open reduction and stabilization are required. Trochanteric portal cephalomedullary nails are recommended if a nail technique is preferred. Piriformis nails may not obtain sufficient stability of the proximal femur. Open plate and screw reduction with an indirect reduction technique may be preferred in this group of patients.
- Russell-Taylor type IIB fractures are the most unstable fractures, with fracture extension into the greater trochanteric region, and have lost medial cortical stability. Trochanteric cephalomedullary nails are the preferred nail option for this group if a stable nail construct can be obtained, or alternatively a 95-degree angle plate and screws. These are very complex fractures to treat with nail techniques, and new locking plate designs may be advised in the future based on future clinical studies.
- Reverse obliquity patterns and lateral wall fractures occurring in the perioperative period have been identified as

**FIG 3** Russell-Taylor classification. Type IA fractures are in reality high diaphyseal femoral fractures within 5 cm of the lesser trochanter. Type IB fractures are fractures at the diaphyseal–metaphyseal junction of the proximal femur with medial instability due to fracture comminution. Type IIA fractures involve the greater trochanter and lateral wall but have the possibility of restoration of medial cortical stability. Type IIB fractures are the most unstable fractures, with fracture extension into the greater trochanteric region, and have lost medial cortical stability.
high-risk patterns for sliding compression hip screw-type implant failure, with secondary displacement and failure to maintain the reduction. This calls into question our ability to differentiate stable from unstable pertrochanteric fractures.4,12

- Determination of the preoperative neck–shaft angle and medullary canal diameter is paramount to selection of the correct nail device, as different manufacturers have different neck–shaft angle and diameter nails. Another important consideration is nail curvature for long nails. Curved nails with a 1.5- to 2-meter radius are applicable to most situations, but the surgeon must beware of patients with excessive curvature or tertiary curves in the distal third of the femur, as distal penetration of long nails has been reported.10

- Cephalomedullary nailing involves fixation of the femoral head coupled with an intramedullary shaft implant (FIG 4). These implants are designed to have a piriformis portal for insertion, usually with the shaft component straight in the AP plane, or a trochanteric portal with the shaft component laterally angulated proximally.

- Modern trochanteric designs have moved to a 4-degree proximal bend positioned above the lesser trochanteric region, which seems to be most compatible with anatomic restoration of the fracture.11

- Reconstruction design nails (two smaller screws into the head) (Russell-Taylor Reconstruction Nail, TriGen; Smith & Nephew) have the usual advantage of a smaller head diameter (average 13 to 15 mm) and may be of a piriformis or trochanteric portal design, whereas the traditional trochanteric portal (Gamma; Stryker-Howmedica), IMHS (Smith & Nephew) nails have a single large-diameter femoral

![FIG 4](image-url)
head fixation screw and have proximal shaft diameters around 16 to 18 mm.

- New-generation trochanteric nails are moving to smaller geometries of 15.5 to 17 mm in diameter to conserve bone stock.
- New designs in femoral head fixation are also in use, with spiral blade nail devices for femoral head fixation (TFN, Synthes) and integrated interlocking two-screw fixation (InterTan, Smith & Nephew) with the design goal of improving fracture stability.

Positioning

- Intramedullary techniques for the proximal femur are best managed with a modern fracture table with image intensification (C-arm) capabilities.
- Although the lateral decubitus approach may be helpful for reverse obliquity patterns, the supine position is usually preferred because of the ease of setup and radiographic visualization in a familiar frame of reference.
- We prefer bilateral foot traction with knees in extension with the legs scissored, although attachment to the fracture table via skeletal traction through the distal femur or proximal tibia is used if there are other injuries about the knee, leg, or foot.
- The operative leg is raised to about 20 to 30 degrees of flexion and the nonoperative extremity is extended 20 to 30 degrees.
- The legs are pulled in line with the body to avoid varus positioning of the hip.
- The C-arm is brought in from the opposite side with the base parallel to the operative extremity, centered on the mid-femur such that the cephalad–caudad movement of the C-arm gives good visualization of the femoral head and shaft in AP and lateral views.
- With this type of setup, the true AP of the hip is usually obtained with 10 to 20 degrees of rotation of the C-arm over the top and the true lateral corresponds to about 15 to 30 degrees over the horizontal position (FIG 5A–C). The lateral decubitus position will also require adjustment of the C-arm to correct parallax error (FIG 5D).

Approach

- The surgical approach for the entry is common for all antegrade proximal femoral nailing.
- The incision is usually 3 to 4 cm long and is about 2 cm proximal to the greater trochanter, centered over the extrapolated middle third of the trochanter.
- In obese or muscular individuals, this can be referenced by a line drawn transversely from the anterior inferior iliac spine and the lateral position of the incision determined by the C-arm true lateral with a radiographic marker on the skin (FIG 6).
- This approach should not damage the gluteus medius muscle, so aggressive traction or manipulation through the muscle should be avoided. The surgeon should always instrument and ream the femur with soft tissue protection in mind.

FIG 6 • Skin incision position referencing the anterior inferior iliac spine.
FRACTURE REDUCTION

- Reduction of the fracture is tantamount to success. My preferred technique for the proximal femur involves a four-step technique.
- After attachment to the foot positioner or skeletal traction with the perineal post attached, posterior sag is corrected at the fracture with a force directed from posterior to anterior and maintained.
- The leg is flexed through the foot holder 20 to 30 degrees from neutral for intertrochanteric personality fractures and 30 to 40 degrees for subtrochanteric personality fractures, maintaining the posterior-to-anterior reduction force at the hip (TECH FIG 1A).
- Traction is applied to restore length in line with the body. No varus!
- The leg is rotated to align with the proximal fragment, 5 to 15 degrees of external rotation for most subtrochanteric personality fractures and 10 to 15 of internal rotation for intertrochanteric personality fractures.
- Acceptable alignment is confirmed with the C-arm in both views. The surgeon ensures there is adequate room in the pelvic and abdominal areas for the insertion of the wires, reamers, and implants in relation to the fracture table. A 3-liter bag of saline may elevate the pelvis high enough to allow room for the instrumentation.
- The reduction can then be fine-tuned with intramedullary instruments or by percutaneous joysticks or pushers (TECH FIG 1B,C).
- If the reduction is not acceptable at this point, the surgeon should stop and re-evaluate the position of the C-arm and the amount of traction (too little or too much). The surgeon should not start reaming the proximal femur until reduction control is demonstrated.
- If reduction cannot be obtained by joysticks and percutaneous bone hooks (TECH FIG 1D), the surgeon should proceed to open reduction using the lower portion of a Watson-Jones-type approach to the hip (TECH FIG 1E-I).
- The surgeon should avoid dissecting the medial soft tissue envelope, where the vascularity is located. A single cerclage wire will be most helpful if there is a coronal split of the proximal fragment. Use of multiple cables or wires is avoided. The clamps and reduction tools are maintained as the implant is inserted.

**TECH FIG 1** • A. Reduction maneuver with force directed posterior to anterior at the fracture to align anterior cortices, flexion of distal fragment to match proximal fragment, and then longitudinal traction. B. Open reduction Watson-Jones with two clamps for irreducible high-energy hip fracture. F. Open reduction AP radiograph. G. Open reduction lateral radiograph. H,I. AP and lateral radiographs showing final result.
PRECISION PORTAL PLACEMENT AND TRAJECTORY CONTROL

- The rationale for the minimally invasive cephalomedullary surgical technique is based on three concepts to maximize bone and soft tissue conservation during nail implantation and to minimize the potential for malalignment\textsuperscript{16}:
  - Precision portal placement
  - Trajectory control
  - Portal preservation
- A precise starting point is the first criterion in ensuring an accurate reduction of proximal fractures, whether the entry portal is a modified trochanteric entry portal or a piriformis portal as defined by the selected nail geometry (TECH FIG 2A,B).
- The proximal femur is filled with a solid cancellous bone architecture from the femoral head region until the level just below the lesser trochanter, where the medullary canal begins.
- Trajectory control is the development of a precise path for the nail through this solid cancellous bone, which will restore the proximal alignment in the anteroposterior and mediolateral planes.
- This correct trajectory parallels the anterior lateral cortex of the proximal femur and allows nail juxtaposition against a solid cortical structure (TECH FIG 2C).
- An incorrect trajectory will induce malalignment with nail insertion and result in an unstable juxtaposition against cancellous bone only, forcing the nail to migrate to the posterior cortex and resulting in a flexion deformity of the proximal fragment (TECH FIG 2D,E).

PORTAL ACQUISITION AND PROTECTION

- Once the correct trajectory is established, the portal and the lateral wall of the trochanter must be protected from erosion and fragmentation by the subsequent instruments for fracture reduction and canal preparation.
- Typically, with the patient in a supine position, this erosion takes place in a posterolateral direction during reaming of the proximal femoral component, further contributing to a flexed and varus position of the proximal fragment when nail insertion occurs.
- A stepwise approach to canal preparation will simplify the nail insertion technique (TECH FIG 3A–C).
- There are three currently published options for portal placement\textsuperscript{14}:
  - Lateral trochanteric for nails with a proximal lateral angulation of more than 5 degrees
  - Medial trochanteric portal for nails with a proximal lateral angulation of 4 to 5 degrees
  - Piriformis portal for straight proximal segment nails
- The guidewire drill system is inserted with soft tissue protection to the region of the greater trochanter. A 3.2-cm guidewire is inserted about 5 to 10 mm into bone in the lateral aspect of the greater trochanter.
- This is a pivot pin about which a honeycomb type of targeter can be adjusted to precisely place the definitive guidewire pin at the tip of the greater trochanter.

- The definitive guidewire should just lateral to the tip of the greater trochanter for the lateral trochanteric portal, medial to the tip of the greater trochanter for the medial trochanteric portal (see Tech Fig 2A), and medial to the trochanter on the nadir of the superior femoral neck for the piriformis portal on the AP C-arm view, and all portals should be centered in the femoral neck on the lateral C-arm view.
- The definitive guidewire should be inserted 10 to 15 mm into the trochanter and does not have to be in correct canal alignment as the definitive trajectory will be obtained in the next step.
- Insertion of the guidewire too deeply will constrain the reamer usually into a varus fracture reduction position. This is because the flexibility of the wire and the lateral approach vector of the hip will always place the wire in a varus position when nailing in a supine position. One of the real advantages of the lateral position is allowing a more direct vector approach for the guidewire.

- A cannulated rigid reamer, preferably with modular end-cutting capability (TriGen), approximating the proximal nail geometry diameter, is introduced over the guidewire through the protective sleeve (TECH FIG 3D).
- The rigid reamer or channel reamer is directed toward a point projected in the center of the medullary canal just distal to the region of the lesser trochanter (TECH FIG 3E).
- The reamer is advanced in stepwise fashion while confirming maintenance of trajectory.
- After the reamer has been inserted about 20 mm, its trajectory is confirmed with a lateral C-arm view.
- The reamer should be directed along the anterior cortex of the proximal femur. The insertion of the reamer can be adjusted during reaming to approximate the position described and is most helpful in avoiding a varus position of the proximal femur.
- Once the canal is reamed in such a fashion, the distal femur is adjusted with the fracture table to allow correct neck-shaft angulation.
- The reamer is inserted until it reaches the medullary canal just below the region of the lesser trochanter (TECH FIG 3F).
- The inner reamer is removed and the outer reamer is maintained for protection of the proximal reamer during the next step.

(A: Courtesy of Smith & Nephew, Inc.)
FRACTURE REDUCTION AND CANAL PREPARATION

- A fracture reducer (TriGen) or similar curved cannulated device is inserted through the retained channel reamer to the fracture site and threaded through the fracture site into the distal fragment intramedullary canal, with manipulation in appropriate planes to align the fracture (TECH FIG 4A).
- A long guide rod is inserted to the knee if a long nail is desired, confirming that the wire does not impinge on the anterior cortex distally.
  - Preferably the guide rod should be inserted to the old physeal scar and centered on AP and lateral C-arm views (TECH FIG 4B).
- The reducer is removed and the guidewire position is maintained with an obturator proximally.
- Length is checked with an appropriate ruler, allowing for fracture distraction and nail final position.
- The diaphyseal region is reamed up to 1 mm over the desired nail size (up to 2 mm for excessive anterior bows) (TECH FIG 4C).
  - The proximal expansion of the nail should have already been reamed with the entry portal reamer, but the surgeon should always confirm diameters.
- The channel reamer is removed and the selected nail is inserted (TECH FIG 4D).

- For long trochanteric nails, it is helpful to rotate the nail 90 degrees anteriorly during the first half of the nail insertion to minimize hoop stresses in the proximal femur. After partial insertion, the nail is rotated to the anticipated anteversion required for femoral head fixation.
- The last 5 cm of the nail is inserted after releasing distraction sufficient for fracture apposition, maintaining correct rotational alignment.
- Most commercial guides use reference marks to align with the femoral head on the lateral C-arm view. These same guides may be used for C-arm verification of correct depth of insertion to allow optimal femoral head fixation.
- The long guide rod is removed to proceed with interlocking.
- Proximal interlocking will depend on the type of implant selected, but most designs recommend that the screw be placed as close to center-center position as possible.
- If a secondary screw is included in the nail design constructs (ie, Reconstruction or InterTan), there is usually sufficient room for the second screw inferiorly, but care should be exercised in small patients.

TECH FIG 4 • A. Insertion of reducer through channel reamer, lateral radiographic view. B. Reducer directed guide rod centered on lateral radiograph, avoiding anterior distal cortex. C. Diaphyseal reaming through channel reamer. D. Nail insertion. For trochanteric nail, the surgeon matches the curve of the nail with the proximal femur during initial insertion to minimize hoop stress at entry portal. The nail is rotated into correct position after 30% to 50% insertion.
SINGLE-SCREW OR SINGLE-DEVICE DESIGNS (GAMMA, IMHS, TFN [SYNTHESES, PAOLI, PA])

- The center-center wire is inserted to within 5 mm of subchondral bone. Fracture reduction is confirmed and the length to lateral cortex is measured.
- If compression is desired (usually 5 mm), the surgeon reams for the screw and selects a screw 5 mm shorter than measured. For the TFN, the head is not reamed.
- The surgeon inserts the head fixation screw or nail to the desired depth; position is confirmed on AP and lateral C-arm views (TECH FIG 5A).
- The option of compression and locking of the lag screw with a set-screw within the nail is available on selected systems (TECH FIG 5B,C).

![TECH FIG 5](image1)

A. Gamma nail AP view with lateral trochanteric portal and center-center head screw position. B. Russell-Taylor IIb fracture with short InterTan nail AP. C. Lateral view.

SINGLE-SCREW OR SINGLE-DEVICE DESIGNS (GAMMA, IMHS, TFN [SYNTHESES, PAOLI, PA])

- Using the proximal targeting guide attached to the nail, the surgeon inserts the most distal proximal guidewire along the femoral calcar within 5 mm of the inferior femoral neck, centered on the lateral C-arm view, to within 5 mm of subchondral bone (TECH FIG 6A).
- Through the proximal targeting guide attached to the nail, the surgeon inserts the most proximal guide pin, which will be close to the center position of the femoral head parallel to the first guide pin. Its position is confirmed with the C-arm.
- The surgeon removes the inferior guidewire, drills and reams for the selected lag screw for the system, and inserts the inferior screw (TECH FIG 6B).
- The same steps are repeated for the proximal screw, and final fixation is confirmed on AP and lateral radiographs (TECH FIG 6C).
- Traction is released before final tightening of the lag screws to allow fracture compression.

![TECH FIG 6](image2)

A. Trochanteric reconstruction nail with inferior drill placed first along medial neck. B. Inferior lag screw placed first. C. Lateral radiographic view of head screw position.
INTEGRATED SCREW CEPHALOMEDULLARY NAIL (INTERTAN)

- Whereas the previous techniques for femoral head fixation used devices that gain compression by impaction or compression against the lateral cortex, this device uses a gear drive mechanism that compresses the nail against the endosteal surface of the medial cortex and simultaneously compresses the proximal femoral head and neck to the medial surface of the nail (see Tech Fig 5B,C).
  - This design conceptually improves rotational and translational stability to the proximal femoral construct.
- The 3.2-mm guidewire is inserted through the proximal targeting guide and advanced in a center position of the femoral head to within 5 mm of subchondral bone, after confirming correct depth and anteversion (TECH FIG 7A–C).
- The inferior lateral cortex is drilled through the targeting guide with a step drill to clear away bone from the nail attachment site for the gear drive. The inferior screw hole is then drilled to within 5 mm of the center-center guidewire tip (TECH FIG 7D).
- The derotation bar is inserted into the inferior hole to augment femoral head and neck stability during large lag screw reaming (TECH FIG 7E,F).
- The surgeon confirms the length for the lag screw, subtracting 5 to 10 mm from the measured length for compression if desired.
- The 3.2 wire is overdrilled with the 10.5-mm cannulated drill, and the selected lag screw is inserted to within 5 mm of subchondral bone (TECH FIG 7G).
- The derotation bar is removed and the compression gear drive screw is inserted through the guide. Traction is released from the leg and compression is started (TECH FIG 7H–K).
- Compression though the gear drive does not begin until the head of the gear drive screw contacts the nail.
- Visualization of compression can be confirmed by C-arm and calibrations on the guide.
- Once compression is achieved, the screwdrivers are disassembled. Static locking of the screw assembly can be achieved with the integrated set screw within the nail.

**TECH FIG 7** • Integrated screw cephalomedullary nail (InterTan, Smith Nephew, Inc.). **A.** Pilot drill hole for 3.2-mm wire for center-center position. **B.** AP radiograph with radiolucent alignment tower. **C.** Lateral radiograph with radiolucent guide centered over femoral head. **D.** Inferior screw hole for derotation bar and compression screw. **E,F.** Derotation bar inserted. **G.** Drill for cannulated center lag screw. (continued)
Short nails have distal locking capability, usually in a static or dynamic mode with most modern designs. I prefer dynamic locking.

- Most systems have this hole targeted through the proximal nail guide, and a single bicortical screw is usually sufficient.

- Long nails have distal locking capability with either static holes or a combination of static and dynamic.

- For length-stable proximal fractures, one bicortical screw is sufficient in a dynamic mode.

- Conversely, for segmental fractures or extensive comminution, two screws may be preferred.

- Distal interlocking is most commonly done using the same freehand technique used in the conventional femoral interlocking nail technique (TECH FIG 8).

**DISTAL INTERLOCKING TECHNIQUE**

**WOUND CLOSURE FOR ALL NAILS**

- With attention to detail, minimal damage to the muscle and skin is incurred with nail techniques, so wound irrigation and standard layered closure are performed.
PEARLS AND PITFALLS

Reduction in the lateral position
- The height of the perineal post is adjusted to effect medial displacement of the shaft. This is especially helpful with reverse obliquity pertrochanteric patterns (Russell-Taylor IIA).

Reduction in the supine position
- The surgeon should avoid placing the hip in varus to gain entry into the bone. This leads to a varus trajectory in the proximal bone stock, which will recur with nail insertion.
- The key to reduction is the rotation of the distal fragment to the externally rotated proximal fragment and apposition of the anterior cortex of the proximal and distal fragments. These two points will allow correction of the flexion and malrotation deformities.
- After nail insertion, the rotational alignment of the proximal femur may change, so before distal interlocking, the surgeon should check length on the lateral C-arm view and match of cortex anteriorly and posteriorly for equivalent thickness. I use a C-arm–verified true lateral view of the hip, mark the rotation of the C-arm on its axis, and then move the C-arm to the distal femur and visualize a true lateral of the knee with overlap of the femoral condyles and mark the rotation of the C-arm. Simple subtraction of these two values gives me the approximate anteversion. For most patients, 15 degrees is the average, although some Asian patients have up to 30 degrees. Then, by rotating the distal fragment, alignment is set and the nail is finally fully seated.

Entry portal
- The medial trochanteric portal greatly simplifies the access to the proximal femur, and the use of a rigid reamer system minimizes false trajectories and trochanteric iatrogenic fractures. The surgeon should avoid letting the reamer lateralize in the greater trochanter at any time.
- The medial trochanteric portal uses less radiation and operative time and is preferred in the supine position.15

Trajectory control
- The concept of trajectory control places the nail in apposition to the anterolateral cortex, minimizing flexion deformities at the fracture site, and conserves bone stock proximally by avoiding cutout of the reamer posteriorly.

Nail insertion
- Rotation of the trochanteric design nails during the first half of insertion minimizes stress on the greater trochanter and medial cortex of the femur below the lesser trochanteric region in long nail designs.
- The surgeon should remember to let off traction before final seating of the nail to avoid nailing the femur in distraction.
- Nails must have stability by cortical contact in the proximal and distal femur. Disruption of the lateral wall places more stress on the construct and should be reconstructed separately from the nail if displaced, or a locking proximal plate may be required. Special care is required for Russell-Taylor IIA and B fracture patterns.

Proximal screw targeting
- Guidewire insertion and drilling should always be performed with a high speed rate and a slow feed rate. This means that the guidewires and reamers bend and can be misdirected with excessive axial force during drilling.
- For single-device and integrated screw femoral head fixation, the surgeon should use a center-center position for the large lag screw.
- For two-device femoral head fixation (reconstruction), the inferior screw is placed first along the lateral wall places more stress on the construct and should be reconstructed separately from the nail if displaced, or a locking proximal plate may be required. Special care is required for Russell-Taylor IIA and B fracture patterns.

Distal locking
- Distal locking is usually recommended with a dynamic single screw for short and long nails. Two distal interlocking screws are recommended for comminuted or segmental fractures.

POSTOPERATIVE CARE
- AP and lateral radiographs of the final construct should be obtained in the surgical suite before recovering the patient to assess the construct and ensure stability.
- If there are adjustments to be made, these are best made while the patient is still under anesthesia.
- Radiographs should reveal the entire fracture region, including the entire implant construct.
- Patients are mobilized to a chair upright position the day after the operative procedure.
- Ambulation with supervision is allowed, with weight bearing as tolerated with a walker or crutches and emphasis on heel-strike and upright balance exercises.6
- Multiple trauma or patients with other complications may have delayed ambulation, but it should begin as soon as possible to minimize secondary complications.
- Patients are re-evaluated with an examination and radiographs at 2 weeks and then monthly thereafter until fracture healing is documented and the patients have maximized ambulatory capabilities, usually by 6 months after the injury.
- The surgeon should emphasize good nutrition and hip abductor exercises bilaterally.
- Patients must be counseled to report any increased swelling or respiratory distress as an emergency because of the high risk of thromboembolic disease.

OUTCOMES
- Union of these fractures is high (more than 95%).
- Functional recovery is poor in many patients, however, with more than 60% of patients failing to recover their preinjury level of function.3
- Mortality within the first year in patients older than 55 is 20% to 30%.
Many patients sustain progressive collapse of the hip into varus and shortening of the leg with the current generation of sliding hip screw fixation.9

**COMPLICATIONS**

- Loss of construct stability is one of the most common complications. It is manifested by collapse of the screw and varus migration of the femoral head construct, with final cutout failure in the worst cases.
  - This occurs to a small degree in all cases, as the sliding impaction was designed to minimize catastrophic cutout.
  - A center-center position of single-screw devices minimizes cutout.3
- Nail cutout is a much more serious complication, involving loss of fixation of the nail component in the proximal femur or periprosthetic femoral fracture with short nails; this will result in reoperation with locking construct plates or 95-degree blade plates, exchange for longer nails, or even prosthetic replacement in severe cases (FIG 7A).
- Nonunion, though rare (1% in older patients), is usually treated with total hip replacement and grafting and implant revision in young patients (FIG 7B).
- Infection occurs in 1% to 2% of postoperative cases and is minimized by preoperative antibiotics, usually a cephalosporin class of antibiotic.
  - In immunocompromised and malnourished patients, standard care involves isolation and sensitivity testing of the causative bacteria and appropriate intravenous antibiotics, in consultation with an infectious disease specialist, and standard débridement and irrigation for wound care.
  - If the implant is stable, it should be retained. Rarely will a resection arthroplasty be required.

**REFERENCES**

Peritrochanteric hip fractures are defined as extracapsular hip fractures, always involving the trochanter and frequently with extension into the subtrochanteric region.

- These fractures occur after falls in a substantial number of elderly people (estimated incidence of 250,000 fractures per year) and represent a growing percentage of healthcare expenditures annually.
- These fractures require operative intervention to achieve stable fracture fixation to allow immediate patient mobilization.

**ANATOMY**

- The intertrochanteric region of the hip is notable for the anatomic transition from the femoral neck to the femoral shaft.
  - The angle subtended by the femoral neck and long axis of the femoral shaft in the coronal plane (the neck–shaft angle) is usually between 120 and 135 degrees in adults.
  - Studies have shown that this angle tends to decrease with age.
- The average femoral neck is anteverted between 10 and 15 degrees (range 0 to 50 degrees) and slightly translated anteriorly (5 to 8 mm) from the axis of the femoral shaft.\(^1^4\)
- The peritrochanteric region of the femur is composed of multiple thickenings of trabecular bone distributed in compressive and tensile groups.\(^4\)
  - The thickest and most structural are the primary compressive trabeculae located along the posterior medial aspect of the femoral neck and shaft, also known as the calcar.
  - Multiple muscle groups attach to this region of the femur:
    - Iliopsoas: attaches to the lesser trochanter and exerts a flexion and external rotation force to the hip
    - Abductors and short external rotators: attach to the greater trochanter
    - Adductors: attach to the femoral shaft distal to the peritrochanteric region
- The blood supply to the peritrochanteric region of the femur is rich and abundant. The medial and lateral femoral circumflex arteries supply the cancellous bone of the trochanteric region through muscle attachments at the vastus origin and the insertion of the gluteus medius.

**PATHOGENESIS**

- In the elderly population most peritrochanteric fractures are caused by a fall onto the lateral aspect of the hip, whereas high-energy trauma produces these fractures in younger individuals.
- Numerous factors, such as structurally weak bone, less subcutaneous padding, and slowed protective reflexes, lead to increased forces on the hip with falls in the elderly population.
- Pathologic lesions in the peritrochanteric region are not uncommon and may lead to pathologic fractures after relatively minor trauma.

**DEFINITION**

- Almost all peritrochanteric hip fractures will heal without intervention. However, owing to the pull of the musculature in this region, the fracture will heal in gross malalignment, leading to subsequent functional limitations.\(^1^6\)
- Early operative intervention of these fractures is undertaken to ensure fracture union in anatomic alignment.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- It is important to elicit the cause of the patient’s fall, as many falls in the elderly population that result in hip fractures are due to medical comorbidities.
- Complaints of hip pain before falling may indicate a pre-existing pathologic process that requires further evaluation.
- A thorough global musculoskeletal examination of the patient is necessary because of the high incidence of associated fractures (especially of the wrist and proximal humerus) in the elderly population sustaining hip fractures from simple falls.
- Examination of the soft tissue overlying the lateral hip, sacrum, and heels is necessary to ensure that no pressure ulcers or abrasions have occurred in these areas.
- The classic physical finding in a patient with a peritrochanteric hip fracture is a short, externally rotated affected extremity.
- Patients may have associated musculoskeletal injuries that are not discovered until examined because of the distracting hip injury.
- Hip rotation assessment: Because of the muscular attachments and gravity, the lower extremity tends to rest externally rotated with a peritrochanteric hip fracture.
- Passive log-rolling of the leg will elicit pain (particularly with internal rotation, which tightens the hip capsule and causes pain due to the hemarthrosis). This may be an especially helpful finding in occult hip fractures with no obvious fracture deformity.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs consisting of an anteroposterior (AP) pelvis and cross-table lateral of the injured hip should be obtained initially.
- A traction radiograph (radiograph taken with gentle manual traction and internal rotation of the leg) will provide more information on the fracture pattern and will allow a better comparison to the uninjured hip (FIG 1A,B).
- A fine-cut (2-mm) CT scan with reconstruction images (sagittal and coronal) set to bone windows may help assess the fracture when ipsilateral femoral neck or other fractures are suspected.
- MRI is the modality of choice to assess for the presence of an occult peritrochanteric hip fracture in the setting of normal radiographs (FIG 1C).
DIFFERENTIAL DIAGNOSIS
- Femoral neck fracture
- Femoral shaft fracture
- Greater trochanter fracture
- Septic hip
- Lateral compression-type pelvic fracture, with pubic rami fractures

NONOPERATIVE MANAGEMENT
- Early operative management of peritrochanteric fractures is associated with decreased patient morbidity and improved patient function compared to nonoperative management.
- Relative indications for nonoperative management include nonambulatory or demented patients with little pain, patients with active sepsis, patients with skin breakdown around the surgical site, and patients with severe and irreversible medical comorbidities precluding operative intervention.
- Nonoperative management consists of two regimens:
  - Early mobilization
    - No attempt at axial realignment
    - Used for nonambulatory patients and consists of pain control and early mobilization out of bed to chair as tolerated to avoid systemic complications of recumbency
  - Traction
    - Attempted anatomic realignment with nonoperative management for ambulatory patients
    - Balanced traction for 8 to 12 weeks, with serial radiographs to assess healing
    - Progressive weight bearing as the fracture shows signs of healing

SURGICAL MANAGEMENT
- Once surgical management is chosen, the timing of intervention becomes important.
- The balance between medical optimization and early operative management in this mostly elderly patient population is delicate.
- Although a recent study of more than 2600 patients found that a delay in surgery of up to 4 days did not increase patient mortality up to 1 year postoperatively, most studies suggest that delays of more than 2 days may increase patient mortality postoperatively.11,17

Preoperative Planning
- Radiographs are reviewed to determine the fracture pattern.
- We find the AO/OTA fracture classification system to be useful and reliable for these fractures. It is divided into groups based on fracture geometry (FIG 2):
  - Group 1 has a single fracture line extending to the medial cortex.
  - Group 2 has more than one fracture line extending to the medial cortex.
  - Group 3 has a fracture geometry that runs in a more transverse or reverse oblique pattern, with the fracture line exiting the lateral cortex below the vastus ridge.
- Implant selection for fracture fixation should be guided based on fracture pattern and patient age.
  - OTA 31-A1-type fractures have been shown to be fixed with reliably good results using either a sliding hip screw or intramedullary device.
  - OTA 31-A2-type fractures have been shown to be amenable to treatment with either side plate and screw devices or intramedullary devices.
  - Recent studies have shown improved patient outcomes and better maintenance of fracture alignment with the use of intramedullary devices in this type of fracture.12,15
  - OTA 31-A3-type fractures have been shown to be treated best with intramedullary devices or blade plates.
  - Sliding hip screw devices are contraindicated in these fractures because of the high incidence of implant failure.6
  - In a meta-analysis, intramedullary implants were found to have a lower failure rate than blade plates when used to treat this type of fracture pattern and should be considered the implant of choice for the elderly patient.6
  - Preservation of bone stock in the proximal femur is an important consideration in young patients with this fracture pattern.
A fixed-angle plate (such as a 95-degree blade plate or locked plate), as well as a reconstruction-type nail with a small proximal diameter, will allow for stable fracture fixation, along with preserved proximal femoral bone stock, which is helpful in cases necessitating later revision open reduction and internal fixation.

The neck–shaft angle of the nonfractured femur should be measured preoperatively to estimate the reduction to be achieved (FIG 3).

Preoperative planning is vital for a satisfactory outcome when a peritrochanteric fracture is fixed with a blade plate.

Multiple views of the nonfractured, contralateral hip and femur, as well as multiple traction views of the fractured hip, are required to properly plan the surgical sequence for this type of fixation.

Positioning

When fixing a peritrochanteric fracture with a sliding hip screw device, the patient is positioned on a well-padded fracture table, with the nonfractured leg carefully positioned in flexion and external rotation in a well leg holder. Alternatively, the patient may be placed in the “scissor” position, with the nonfractured leg extended and supported with a boot. This position is helpful in some patients (eg, obesity, stiff contralateral hip, bilateral injuries) who may not be able to flex and externally rotate the contralateral hip to enable use of a well leg holder.

This facilitates access by the fluoroscopic C-arm to the fractured hip (FIG 4A).

We prefer to secure the affected foot to a well-padded heel cup with tape, leaving the posteromedial neurovascular bundle uncompromised. The foot is then dorsiflexed and secured against a well-padded metatarsal bar to lock the transverse tarsal joint and allow strong traction and rotational forces to be transmitted to the fracture (FIG 4B).

Alternatively, if the fracture is to be fixed with a fixed-angle plate, the patient is placed on a completely radiolucent flat-top table. The affected hip is bumped up at a 20- to 30-degree angle and the leg is draped free.

The scissors position is another alternative position for fixation of a peritrochanteric hip fracture (FIG 4C). The patient is placed supine on a traction table and both feet are secured in traction boots. The noninjured leg is then extended to allow a lateral radiograph of the injured hip to be obtained with relative ease.

Some muscular patients may require skeletal traction of the affected leg through the distal femur or proximal tibia to provide adequate fracture length and alignment.

Approach

Because of the muscular forces exerted on the fracture fragments associated with peritrochanteric hip fractures, perfect anatomic reduction of the fracture is close to impossible with indirect methods, especially in the lateral plane, which is often the most difficult plane to control.

Studies have shown, however, that absolute anatomic reduction of all fragments of these fractures is not necessary for a satisfactory functional outcome.13

The primary goal of reduction of peritrochanteric hip fractures is to re-establish a normal anatomic alignment between the proximal head and neck fragment and the distal femoral shaft in the anteroposterior, lateral, and rotational planes.

A lateral approach to the proximal femur is the preferred approach for open reduction and internal fixation of peritrochanteric femur fractures.
INCISION

- The incision is centered over the lateral aspect of the femur. It is started proximally at the palpable vastus ridge for sliding hip screw devices and just proximal to the tip of the greater trochanter for fixed-angle plates.
  - The distal extent of the incision is made long enough to allow application of the plate.
- The incision is carried through the fascia lata, avoiding the tensor muscle proximally and anteriorly. The vastus lateralis fascia and muscle is incised longitudinally 2 to 3 cm anterior to the linea aspera and retracted anteriorly. Care is taken to identify and control any perforating vessels supplying the vastus lateralis muscle.
- Proximally, the origin of the vastus lateralis is sharply released off the vastus ridge to allow atraumatic anterior retraction of the muscle, to facilitate lateral femoral shaft exposure.
- Care should be taken to avoid any medial shaft dissection to maintain the vasculature to the fracture zone.

FRACTURE REDUCTION

- With the patient accurately positioned on the fracture table, the fracture is initially reduced in the anteroposterior plane with axial traction to re-establish fracture length and partially correct the varus malalignment (TECH FIG 1).
  - Abduction of the leg usually corrects the final varus malalignment and establishes the normal neck-shaft angle.
  - Internal rotation of the distal fragment usually corrects the external rotation deformity and will align the femoral neck parallel to the floor to assist in eventual guide pin insertion, but this must be confirmed under fluoroscopy.
  - In some instances, external rotation of the proximal fragment is necessary to achieve reduction of the rotational deformity.
- Fracture reduction is next checked in the lateral plane. These fractures often display an apex-posterior angulation. This can be corrected by placing a crutch under the femoral shaft for support. Alternatively, some fracture tables have padded attachments to support the thigh.
  - Fracture reduction is reassessed in both the anteroposterior and lateral planes and checked for fracture displacement, neck-shaft angle, neck anteversion, rotation, and femoral shaft sag, with a goal of obtaining a near-anatomic reduction in all of these planes (normal or slight valgus reduction, less than 20 degrees of angulation on the lateral radiograph, and less than 4 mm of fracture displacement).1
  - If a near-anatomic closed reduction cannot be obtained, a formal open reduction is necessary.
GUIDE PIN POSITIONING FOR SLIDING HIP SCREW AND FRACTURE PREPARATION

- The entrance point for the guide pin is selected once exposure of the lateral femoral cortex is completed.
- The entrance for a 135-degree plate is typically 2 cm below the vastus ridge, opposite the midpoint of the lesser trochanter, at the level of the femoral insertion of the gluteus maximus tendon (TECH FIG 2).
- The entrance point for the guide pin is adjusted 1 cm proximal (for lower-angled devices) or distal (for higher-angled devices) from the 135-degree starting point for every 5-degree adjustment in the measured neck-shaft angle.
- The femoral anteversion can be estimated by advancing a free guide pin by hand up the anterior femoral neck and securing it in the anterior aspect of the femoral head.
- The correct-angled guide is placed at the guide pin insertion site, centered in the anteroposterior plane on the femoral shaft and seated flush to the lateral cortex.
- The guide pin is advanced under fluoroscopic guidance, in both the anteroposterior and lateral views, to ensure central placement in the femoral head.
- If the pin is not centered in the head on both views, it must be removed and adjusted.
- The fracture reduction should be reassessed and the guide adjusted to ensure that central guide pin placement is obtained.
- The guide pin is inserted to within 5 mm of the joint line in both the anteroposterior and lateral projections.
- The interosseous length of the guide pin is measured with the ruler provided in the instrument set.
- Care must be taken when deciding on a lag screw length, especially in highly unstable fractures reduced with a substantial amount of traction. This traction can cause fragment distraction and overestimation of lag screw length, which will be noticed when traction is eventually released.
- The guidewire is then advanced into the subchondral bone to ensure stability during reaming.
- A second guide pin can then be advanced into the femoral head proximal to the original guide pin in

unstable fractures or in fractures that are reduced in anatomic alignment using excessive traction.  
- This pin acts as a derotational pin to ensure that the proximal neck and head fragment does not rotate with reaming and screw insertion.
- A triple reamer is used to prepare the channel in the lateral cortex, neck, and head for the lag screw and side plate barrel.  
  - The reamer is set to 5 mm less than the measured lag screw length to ensure that the subchondral bone in the femoral head is not violated during reaming.
  - The triple reamer is then advanced and withdrawn under fluoroscopic guidance, ensuring that the guide pin is not inadvertently advanced into the pelvis, the channel is reamed to its proper length, and the guide pin is not withdrawn with the reamer.
- Occasionally the intact lateral wall of the proximal femur may be fractured by the triple reamer. If this occurs, the fracture is essentially converted into a transverse or reverse oblique pattern, and excessive fracture collapse will occur if it is fixed with a simple sliding hip screw. In these cases, the proximal lateral wall may be buttressed with the addition of a trochanteric plate in conjunction with a sliding hip screw or conversion to an intramedullary device for fracture fixation.

IMPLANT INSERTION

- A two- to four-hole side plate is usually chosen for fixation (TECH FIG 3).
  - Multiple clinical and cadaveric studies have shown no difference in the strength of implant fixation with side plates with more than four holes.\textsuperscript{3,9}
  - The implant is set up according to the manufacturer's specifications.
  - The cannulated lag screw is then inserted over the guide pin with a centering sleeve to ensure proper positioning. Careful sizing of the lag screw is required, as noted earlier, to ensure that fracture compression does not lead to excessive screw length and lateral hardware prominence.
- Fluoroscopy and manual fracture palpation is used to ensure that the fracture is not displaced (rotated) while the lag screw is inserted.
  - If the fracture is displaced by the insertion of the lag screw, it is removed, the channel is tapped, and the lag screw is reinserted.
  - Peritrochanteric fractures of the right hip tend to displace to an apex-posterior angulation with lag screw insertion, whereas left hip fractures tend to displace to an apex-anterior angulation owing to the anatomic configuration and subsequent tensioning of the hip capsule with screw insertion.
BLADE PLATE INSERTION

- With the lateral femur and trochanteric block exposed, a soft tissue-sparing reduction of the trochanteric block to the proximal femur is secured with pointed bone clamps and K-wires or small lag screws as needed (TECH FIG 4).
- Guide pins are then introduced into this reconstructed segment to facilitate proper seating of the chisel for the blade plate.
  - The first pin is placed anterior to the femoral neck and secured into the anterior femoral head to demonstrate the femoral anteversion.
  - The second pin is placed with the use of an angled guide, fluoroscopy, or both near the tip of the greater trochanter and directed into the femoral head at a 90-degree angle to the femoral shaft once the fracture has been reduced and the neck-shaft angle restored.
- The chisel is inserted parallel to the two guide pins, just distal to the second pin. Care must be taken to maintain the correct alignment of the chisel with the shaft of the femur because this determines the flexion-extension of the fracture, which is fixed once the blade plate is inserted.
- The chisel is aimed to pass through the center of the neck and seat in the inferior portion of the femoral head. Because of the anterior translation of the femoral head on the shaft, the insertion site is in the anterior half of the trochanter.
- The position of the chisel should be constantly checked with fluoroscopy before and during its insertion.
- The chisel is carefully removed and the appropriate-length blade plate is inserted and gently seated into the proximal fragment.
- The insertion should be frequently checked with biplanar fluoroscopy to ensure that the blade follows the path made by the chisel.
- Once the blade is seated, the most proximal screw is placed through the implant into the medial cortex of the proximal fragment.
- Fracture reduction is now achieved by bringing the plate to the shaft and controlling length and rotation.
- A femoral distractor may be used on the lateral aspect of the femur, with the proximal pin in the head and neck fragment and the distal pin placed distal to the end of the plate.
- Distraction is applied across the fracture to gain fracture alignment and length through soft tissue tensioning using an indirect reduction technique.
- A bone clamp is loosely applied to the distal femoral shaft fragment and plate to counteract the tendency...
for the fracture to be reduced into varus with the femoral distractor.
- Pointed reduction clamps are used to reduce comminuted fragments to the plate without stripping them of soft tissue attachments.
- With the fracture alignment and length restored, it is checked with fluoroscopy.
- If acceptable, the distraction is reduced to allow fragment settling and fracture compression.

The plate is then fixed to the shaft fragments with screws in the standard manner, and lag screws are inserted where the pointed reduction clamps were previously placed.

The final fracture alignment and length, as well as the femoral head, are examined with fluoroscopy to ensure proper fracture reduction and to make sure that there has been no head penetration by the implant.

- Aggressive débridement of devitalized tissue is performed before wound irrigation.

The wound is then closed in a layered fashion; the muscle, fascia, subcutaneous tissue, and skin are repaired separately.

**PEARLS AND PITFALLS**

| Preoperative fracture assessment | The fracture pattern must be studied preoperatively so that the proper device for fixation may be chosen. Improper use of a sliding hip screw in an OTA type 31-3A fracture, for example, will lead to a higher incidence of fixation failure. |
| Fracture reduction | Fracture reduction obtaining anatomic alignment is important. The rate of fixation failure increases, no matter what fixation method is used, for poorly reduced fractures. |
**Implant selection**
- Measurement of the neck–shaft angle of the normal hip is important to ensure that the proper-angled side plate is used. Use of an improperly angled device will prevent central and deep placement of the lag screw in the femoral head and will increase the incidence of fixation failure.
- Many different device systems exist with slight variations of technique and implant design. Familiarity with the selected device is important, and a trial run on a plastic bone model can be helpful.

**Lag screw position**
- Positioning of the lag screw centrally and deep within the femoral head is one of the most important factors to protect against implant cutout.
- The tip–apex distance, as measured on anteroposterior and lateral fluoroscopy intraoperatively, should be under 25 mm to significantly decrease the incidence of fixation failure (FIG 5).

**Lateral cortical wall fracture**
- Careful handling and maintenance of the lateral cortical wall of the femur in the trochanteric region is important to provide a lateral buttress for controlled fracture impaction postoperatively. Fracture of this structure during implant insertion may lead to a higher incidence of fracture collapse and poorer outcomes when a sliding hip screw is used for fracture fixation. When this pitfall is encountered, re-establishing the lateral cortex is critical and can be accomplished by adding a trochanteric plate to the sliding hip screw or conversion to an intramedullary device.

**Lateral view reduction**
- Reduction of peritrochanteric fractures in the lateral view is difficult. Gravity and muscular pull tend to the fracture into an apex-posterior or apex-anterior position, respectively, depending on the fracture pattern. Care must be taken to assess the fracture reduction in this plane and adjust the reduction if it is not anatomic. Pointed reduction clamps or percutaneously placed joysticks can aid in the reduction in this plane while limiting soft tissue disruption of the fracture.

**Rotational fracture reduction**
- Rotational reduction of peritrochanteric fractures can be challenging as well. Rotational reduction of intertrochanteric fractures is usually straightforward, as most times there is a major fracture line to assess. Subtrochanteric fractures in young patients are often quite comminuted and lack definitive anatomy to accurately judge rotation alignment from the fracture alone. In these cases rotation malalignment of the limb can be assessed by aligning the hip and knee in the anteroposterior plane. This will ensure overall reduction of any rotational malalignment of the limb.

---

**POSTOPERATIVE CARE**
- Anteroposterior and lateral radiographs of the operative hip should be obtained immediately postoperatively in the recovery room to assess implant position and fracture reduction and to ensure that no iatrogenic femur fracture was produced intraoperatively. The entire device should be included in the radiograph (FIG 6).
- Patients are mobilized as soon as their cardiopulmonary and mental status will safely allow, usually by postoperative day 1.
- Unrestricted immediate postoperative weight bearing is easiest for the patient to comply with, and multiple investigations have shown no increase in fixation failure as a result of this postoperative rehabilitation protocol.
Koval et al used gait analysis to show how patients effectively autoregulate their weight bearing postoperatively, with the patients who had the least-stable fracture patterns preoperatively putting the least amount of weight on their legs immediately postoperatively.

- Patients should be seen 2 weeks postoperatively to check for uneventful wound healing.
- Follow-up radiographs should be obtained at 2, 6, and 12 weeks to check for controlled fracture impaction, exclude any fixation device complications, and assess fracture healing.

OUTCOMES

- With proper fracture reduction, implant selection, and fixation device positioning, peritrochanteric hip fractures heal in up to 98% of cases.
- One-year mortality rates after fixation of peritrochanteric hip fractures range from 7% to 27%, with most studies finding a rate of 15% to 20%.
- Mortality rates depend on both preoperative and postoperative medical complications and condition, as well as preoperative functional status.
- Postoperative functional status also depends on numerous variables:
  - Socioenvironmental functional status has been shown to be of great importance in determining the postoperative function status of a patient.
- Longitudinal studies comparing the functional status of patients before and after hip fracture fixation have documented that roughly 40% of patients maintain their preoperative level of ambulation postoperatively.
  - Another 40% of patients have increased dependency on ambulation devices but remain ambulatory.
  - Twelve percent of patients become household-only ambulators, and 8% of patients become nonambulators postoperatively.

FIG 6 • Postoperative AP and lateral radiographs showing correct implant positioning and no intraoperative complications.

FIG 7 • A. Varus collapse. B. OTA 31-A1 intertrochanteric hip fracture fixed with a sliding hip screw. C. Follow-up radiograph 6 months postoperatively showing secondary fracture displacement.
COMPLICATIONS

- Loss of proximal fixation is defined as varus collapse of the proximal fracture fragment with cutout of the lag screw from the femoral head (FIG 7A). This complication is seen in 4% to 20% of fractures, usually within 4 months of surgery.
- Although certain fracture patterns have been shown to have a higher rate of proximal fixation loss, the fracture pattern cannot be controlled by the physician.
- The placement of the lag screw, on the other hand, can be controlled by the physician. A central and deep position with a tip–apex distance of less than 25 mm has been shown to significantly reduce the incidence of proximal fixation loss.2
- Nonunion occurs in 1% to 2% of fractures. The low incidence is likely due to the well-vascularized nature of the cancellous peritrochanteric region of the hip through which these fractures develop.
- Secondary fracture displacement
  - Despite adequate fracture reduction and implant positioning, fractures may progress to excessive impaction, with resultant limb shortening and abductor weakening (FIG 7B,C). This can lead to suboptimal patient functional results. This is often seen in cases of unrecognized lateral wall fractures (either iatrogenically induced by implant placement or unrecognized from the original trauma).
  - Use of intramedullary fixation devices and vigilant follow-up may help avoid this complication.
- Infection
- Wound dehiscence

REFERENCES

Retrograde femoral nailing can be defined as any femoral nailing technique with a distal entry from the condyles or through an intercondylar, intra-articular starting point. For this chapter, retrograde femoral nailing will refer to nails with an intercondylar starting point that extend through the shaft region to the proximal femur. In certain fracture situations, shortened nails (supracondylar nails) can be used with the same starting point for fixation of distal femoral fractures.

ANATOMY

- The femoral shaft is tubular in shape over the extent of the isthmus, gradually flaring infra-isthmally into the distal femur, which is trapezoidal in cross section.
- The entry point for the retrograde femoral nail is located at the distal end of the patellofemoral groove, just anterior to the posterior cruciate ligament insertion (FIG 1A).
- Radiographically, this is located in the midline or just medial to the midline between the condyles on the anteroposterior (AP) view, and laterally just anterior to the line of Blumensaat as it meets the trochlear groove (FIG 18.C).4,11,13,14,19 This flat articular area has minimal to no contact with the patella until 120 degrees of flexion.1,4
- Pertinent proximal anatomy includes neurovascular structures anterior to the proximal femur, close to interlocking screw insertion sites.21
  - The femoral artery is medial to the proximal femur, with branches that cross the anterior femur more than 4 cm distal to the lesser trochanter.
  - Branches of the femoral nerve cross more proximal starting 4 cm distal to the piriformis fossa.
  - Damage to neurovascular structures caused by proximal locking screw insertion can be avoided or minimized by avoiding medial dissection and with placement at or above the lesser trochanter (FIG 2).

PATHOGENESIS

- Femoral shaft fractures are markers of high-energy injuries.9,11,12,20,24
- Studies have shown that 38% of trauma patients diagnosed with a femoral shaft fracture have additional injuries.4,6,7,23
  - In femur fracture patients with associated injuries, the most common findings are other musculoskeletal injuries (93%), thoracic injuries (62%), head injuries (59%), abdominal injuries (35%), and facial injuries (16%).7
  - Ipsilateral femoral neck fractures occur in 1% to 6% of all femoral shaft fractures and are initially missed in up to 20% to 50% of cases.26 Recognition of these injuries before intramedullary stabilization is important to minimize potential complications (refer to section on imaging and other diagnostic studies).
- All trauma patients should undergo the standard advanced trauma life support (ATLS) examination to rule out associated life-threatening injuries.
- Although less common, femoral shaft fractures can occur in isolated sports injuries and in low-energy injuries associated with pathologic bone, such as with osteoporosis or metastatic bone disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pain and deformity of the thigh are usually obvious but may be obscured in the morbidly obese patient.
- The fractured limb should be closely examined to avoid missing any open wounds, particularly in the posterior aspect of the thigh. Skin abrasions and apparently minor wounds should be assessed to determine if they communicate with the fracture.
- Swelling is a common finding with femoral shaft fractures. Compartment syndrome of the thigh is rare but can occur.25
- The entire lower extremity and pelvis needs to be evaluated because of the high rate of associated musculoskeletal injuries.
- A thorough neurologic and vascular examination must also be performed. Although femoral nerve damage is very unusual, sciatic nerve damage can occur.1,3,32
- Associated ligamentous injuries of the knee are common but may be difficult to assess until definitive stabilization of the femur has been obtained. Therefore, this examination should be repeated after nailing the femoral fracture.28,29

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior (AP) and lateral radiographs of the full length of the femur are essential, as well as formal AP and lateral radiographs of the hip and knee.
- Lateral knee radiographs should be closely evaluated for subtle patellar impaction fractures or nondisplaced fractures.
- Hip radiographs should be closely examined to rule out an associated femoral neck fracture, which has been shown to occur in 1% to 6% of femoral shaft fractures.26
- Some surgeons recommend a routine CT scan examination of the femoral neck as part of the trauma scan to rule out a femoral neck fracture.
- A reported 20% to 50% of these injuries are missed on the initial plain radiographic examination.26
- Because of the high association of missed coronal fractures in high-energy injuries, a CT scan of the knee should be obtained whenever formal knee radiographs reveal a supracondylar distal femur fracture and there is consideration for retrograde nailing.16
- Any coronal fractures seen on CT examination should be considered a contraindication for retrograde nailing owing to increased risk of compartment syndrome.
to the possibility of compromising the distal interlocking screw fixation.

**SURGICAL MANAGEMENT**

**Classifications and Relative Indications**

- It is important to assess the extent of the fracture both proximally and distally with proper radiographs.

- Proximally, CT scans can supplement plain radiographs to determine fracture line extension into the peritrochanteric region and to check for occult femoral neck fractures.

- Distally, CT imaging is helpful to assess intra-articular extension and to check for coronal plane fractures.

- All femoral shaft fractures, as classified by the Winquist system, are technically suitable for retrograde femoral nailing (FIG 3).

- Retrograde femoral nailing is not considered to be the standard of care for treatment of more proximal subtrochanteric fractures, but in certain patient circumstances it may be the treatment of choice (Table 1).

- Subtrochanteric fractures with the lesser trochanter and piriformis fossa intact, Russell-Taylor IA fractures (FIG 4),

May be amenable to retrograde femoral nailing if other patient factors favor a retrograde approach.

- Ideally, some proximal medial cortex remains intact to act as a buttress against the nail.
- It is important to know how far the proximal interlocking screw holes are from the tip of the nail in the retrograde nail system available in your hospital.
- We recommend being able to obtain two bicortical interlocking screws above the most proximal fracture line for very proximal fractures. If possible, they should be through holes, not slots, in the nail to provide more stability.
- If the subtrochanteric fracture has proximal extension, including either the lesser trochanter or piriformis fossa, or both, then proximal interlocking screw fixation of the retrograde nail would be compromised and alternative fracture fixation methods should be considered.
- Retrograde femoral nailing may be considered in certain supracondylar distal femoral fractures. We find that Muller’s AO classification system of distal femoral fractures best elucidates which of these fractures can be addressed with retrograde femoral nailing (Fig 5).
- Consideration for retrograde femoral nailing can be given for all extra-articular (A subgroup) fractures.
- It is important to know the distance between the distal interlocking screw holes and the tip of the nail in the retrograde nail system available in your hospital.
- We recommend being able to obtain at least two bicortical interlocking screws below the most distal fracture line for distal fractures.
- Nails with oblique distal interlocking options can be advantageous because of increased stability and potentially less screw head prominence.
- Consideration for retrograde femoral nailing can be given to simple transverse articular fracture patterns (C-1 and C-2 subgroups).
- This should be performed with an open medial or lateral parapatellar approach to the knee in lieu of a percutaneous approach. Articular reduction must first be obtained and then maintained with bicortical screw fixation.

Chapter 9 RETROGRADE INTRAMEDULLARY NAILING OF THE FEMUR

FIG 5 • Muller's AO classification system of distal femoral fractures,15 with fracture patterns amenable to retrograde femoral nailing highlighted.

FIG 6 • A. Diagram of lateral aspect of distal femur, with potential sites for intra-articular screw fixation out of the path of the retrograde femoral nail identified. B. Diagram of distal femur end on, with potential sites for intra-articular screw fixation out of the path of the retrograde femoral nail identified. C. Intraoperative lateral radiograph of a supracondylar, intracondylar (C1) distal femur fracture with intra-articular screw fixation and retrograde nail in place.

placed outside of the planned path for the retrograde nail (FIG 6).

• Partial articular fractures (all B subgroups) and complex articular fractures (C-3 subgroups) should not be considered for retrograde femoral nailing.

• Patients with osteoporotic distal fractures may be best treated with some of the newer fixed-angle plate devices, owing to concerns of distal interlocking screw purchase.

• Alternatively, nails designed with multiaxial screws or the use of supplemental blocking screws may help with augmenting fixation.

Contraindications

• Preoperative knee stiffness preventing 40 to 60 degrees of flexion

• Active knee sepsis

• Grossly contaminated soft tissue wounds about the knee

• Skeletally immature patients

Preoperative Planning

• AP and lateral radiographs are used to measure the diameter of the femoral canal isthmus and thus determine the approximate nail diameter. Most intramedullary nail systems come in diameters ranging from 10 to 13 mm.

• Nail lengths are often determined intraoperatively but can be ascertained by imaging the contralateral femur.

• Radiographs are evaluated to determine the location and morphology of the fracture; they should be scrutinized for nondisplaced secondary fracture lines that could become displaced during operative treatment.

• Occasionally, fracture fragments may be stuck in the canal and may need to be pulled out.

• In the case of fractures that show significant shortening preoperatively, it may be difficult to restore length off the fracture table.
A trial reduction should be performed under fluoroscopy before the start of the procedure; the patient must be paralyzed for the procedure.

If length is difficult to restore manually, then a femoral distractor should be used for the procedure. Placement of the femoral distractor is described in the section on fracture reduction.

Before preparing and draping the injured limb, the surgeon should examine the contralateral extremity to determine the patient’s normal leg length and rotation.

Femoral length can be evaluated by using a radiographic ruler and intraoperative fluoroscopy (FIG 7A).

Normal rotation can be determined by flexing the hip and knee and checking the patient’s normal internal and external rotation of the hip, and by examining the normal resting position of the foot as the patient lies supine on the operating room table (FIG 7B).

Positioning

The patient is positioned supine on a radiolucent diving board or flat-top table with no bump under the hip.

The surgeon should ensure that the entire femur, from hip to knee, can be imaged on AP and lateral fluoroscopy.

The extremity should be draped free from the anterior superior iliac spine to the ankle. The entire hip should be included in the preparation in case any femoral neck fractures are identified after treatment of the femoral shaft fracture.

Radiolucent sterile towels, sheets, or a radiolucent triangle are used to create a bump under the knee, allowing for about 40 degrees of knee flexion and placing the patella anterior for correct rotational alignment.1,14

Intraoperative fluoroscopy should come in from the contralateral side.

Approach

The knee should be flexed about 40 degrees to avoid injury to the proximal tibia and the patella.14

Intraoperative fluoroscopy is used to obtain a perfect lateral of the knee. The line of Blumensaat should be clearly identified (see Fig 1C).

A radiopaque guidewire can be used to identify the center of the long axis of the femur in order to determine the correct level of the skin incision.

The guide pin is used to center a 1.5- to 2.5-cm incision just medial to the midline.

A medial flap is created using subcutaneous dissection. A medial paratendinous arthrotomy is then made to allow entrance of the initial starting guidewire into the intracondylar notch.

FIG 7 • A. Schematic lateral view of a patient on a radiolucent operating room table, depicting how to use a radiopaque ruler and fluoroscopy to determine femoral length. B. Schematic anterior view of a patient on the operating room with the uninjured hip and knee flexed, checking the patient’s normal internal and external rotation of the hip.
PLACING THE GUIDEWIRE
- The surgeon confirms the correct placement of the initial starting guidewire on the AP and lateral fluoroscopic radiographs.
  - On the lateral image, the initial starting guidewire should be situated at the apex of the line of Blumensaat, in line with the femoral shaft (see Fig 1C).
  - On the AP image, the guidewire should be centered or just medial to the midline in the trochlear groove, in line with the femoral shaft (see Fig 1B).
  - On the AP image, the fluoroscope is moved proximally to be certain the guidewire is directed at the center of the canal.
  - When starting to drill the initial guidewire, the surgeon’s hand should drop slightly to prevent the wire from falling into the posterior cruciate ligament insertion; the hand is raised once the wire enters the cortex, so as to be in line with the femoral shaft.
  - Once the initial starting guidewire is centered on the AP and lateral images, the wire is passed into the distal femoral shaft.
  - A soft tissue retractor is placed over the initial starting guidewire to protect the patellar tendon during reaming.

CREATING AND REAMING THE STARTING HOLE
- The initial starting reamer is used to create the starting hole. (Alternatively, an awl or a step drill can be used to make the starting hole using the principles described above.)
  - Once the starting hole has been made, a beaded-tip guidewire is passed to the level of the fracture.

FRACTURE REDUCTION
- Traction is used to restore length. The surgeon must ensure that adequate anesthesia (full paralysis) is employed.
  - There are many deforming muscle forces, depending on the level of the fracture. If the fracture cannot be reduced by manual traction, use of bumps, pulling with sheets wrapped around the proximal or distal thigh, or pushing with mallets, then here are some options.
  - The abductor muscles will abduct and externally rotate the proximal femur after high subtrochanteric and proximal shaft fractures. Inserting a unicortical 5-mm Schanz pin through a percutaneous incision in the lateral cortex just above the fracture or in the greater trochanter can gain excellent control of the proximal fracture fragment.
  - The iliopsoas muscle will flex and internally rotate proximal-third femoral shaft fractures by its pull on the lesser trochanter. Again, inserting a unicortical 5-mm Schanz pin through a percutaneous incision in the lateral cortex just above the fracture or in the greater trochanter can gain excellent control of the proximal fracture fragment.
  - The adductor muscles span most shaft fractures and exert a strong axial and adduction force. Sometimes mid-shaft transverse fractures can be the most difficult to reduce. Inserting a unicortical 5-mm Schanz pin through a percutaneous incision in the lateral cortex just above and just below the fracture can gain excellent control of the proximal and distal fracture fragments.
  - Distal fractures tend to angulate into recurvatum through the pull of the gastrocnemius muscle. Bumps placed under the knee to flex the knee can help relax the gastrocnemius muscle. One can also use blocking screws in distal fractures to surgically create a narrow “canal” in the metaphyseal region in line with the canal of the femoral shaft so that the intramedullary nail can help with reduction of the fracture.
  - Alternatively, a femoral distractor can assist with obtaining and maintaining fracture reduction for a fracture at any level. It can be placed laterally, inserted proximally at the greater trochanter and distally in either the posterior aspect of the femoral condyle or in the proximal tibia. Alternatively, some surgeons recommend anterior placement to avoid potential posterior angulation of distal fracture patterns.
  - Lastly, some fractures require opening of the fracture site to obtain reduction, with the finding of the muscle interposed within the fracture. We recommend laterally based incisions unless otherwise dictated by an open fracture wound.
  - Restoration of length and correct rotation can be assessed clinically as well as radiographically by closely scrutinizing the diameter of the medial and lateral femoral cortex, ensuring they are of equal diameter proximal and distal to the fracture.

PASSING THE GUIDEWIRE
- Once the fracture is reduced on the AP and lateral images, the surgeon passes the guidewire to end just below the level of the piriformis fossa.
  - This is done to ensure that reaming is performed past the level of the lesser trochanter, since the reamers stop at the beaded portion of the guidewire.
REAMI NG

- Reaming should begin with an end-cutting reamer (typically size 8 mm or 9 mm in diameter).
- Fracture reduction must be maintained throughout the reaming process to minimize eccentric reaming.
- Reaming should be performed slowly and in 0.5-mm increments to prevent thermal necrosis.
- The approximate nail diameter is selected based on the preoperative measurement of the femoral isthmus. The final nail diameter should be selected based on the size of the reamer that provides the initial cortical chatter.
- The canal is reamed to 1.0 to 1.5 mm over the selected nail diameter.
- Nail length can be determined multiple ways:
  - A radiolucent ruler can be placed on the anterior aspect of the femur. The nail should end above the level of the lesser trochanter on the AP radiograph and should be measured so that it is deep to the apex of the line of Blumensaat on the lateral view (see Fig 1C).
  - Alternatively, a second guidewire of the same length can be inserted into the knee to end just deep to the apex of the line of Blumensaat on the lateral fluoroscopic image.
  - This additional guidewire is clamped at the level of the guidewire already in place.
  - The portion distal to the guidewire in place is measured to equal the amount of guidewire in the femoral canal (TECH FIG 1).
  - In addition, many nailing systems have system-specific measurement guides that are outlined in their technique manuals.
  - If the measurement is between nail sizes, the shorter nail is selected. Length can be added with an end cap if required.

PLACING THE NAIL

- Once the nail size is selected, the nail is inserted over the guidewire.
- Most current systems allow the beaded-tip guidewire to pass through the cannulated nail. If an older system is being used, then the beaded-tip guidewire must be exchanged for a smooth-tip guidewire using an exchange tube.
- If guidewire exchange is required, the surgeon ensures correct placement of the smooth-tip guidewire on the AP and lateral images before nail insertion.
- The nail is inserted over the guidewire and should pass relatively easily.
  - If the nail does not advance easily, the surgeon performs a careful AP and lateral fluoroscopic assessment of the fracture reduction and nail placement.
- Nail insertion depth is assessed on the lateral knee radiograph.
  - The nail should end proximal to the apex of the line of Blumensaat to ensure subchondral placement (TECH FIG 2A).
  - The surgeon confirms that fracture length and alignment have been restored on the AP and lateral radiographs.
- The surgeon confirms that the nail length selected puts the proximal tip of the nail ending at or above the level of the lesser trochanter (TECH FIG 2B).
  - The nail is advanced if the proximal tip does not end at or above the level of the lesser trochanter.
- If this leaves the nail countersunk, end caps can be selected to gain nail length.
- Care must be taken to remain below the piriformis fossa to avoid proximal nail protrusion.
- The nail is locked distally using the distal interlocking guides.
- We typically use one lateral-to-medial distal interlocking screw for transverse midshaft femoral fractures, and a second anterolateral-to-posteromedial distal interlocking screw for comminuted or distal femoral fractures.
- Using live fluoroscopy, the fluoroscopic machine is rotated about the knee to assess the length of the interlocking screws. Because of the trapezoidal shape of the distal femur, screws are often prominent but not well recognized on the AP radiograph.
- The surgeon should consider using washers, a medial locking nut, or a locking end cap (which locks the most distal interlocking screw to the nail) as options for osteoporotic bone.
- Once distal interlocking screw fixation is complete, the surgeon reassesses the fracture reduction fluoroscopically.
- If any shortening has occurred, length can be regained by manual traction or by back-slapping the nail with the insertion guide nail removal attachment (the surgeon must exercise caution when using this technique in patients with osteoporotic bone).
Proximal interlocking screw fixation is performed in the anterior-to-posterior plane using the freehand perfect circle technique. First, a magnified AP image of the proximal femur is obtained. The fluoroscopy machine is rotated until the proximal interlocking hole is seen as a “perfect circle” (also discussed in Chapter TR-10, Anterograde Intramedullary Nailing of the Femur; Tech Fig 4, Distal interlocking screw placement). A 1-cm incision is made in the proximal aspect of the thigh, anteriorly centered over the proximal interlocking hole, as visualized on the AP radiograph. Careful blunt dissection exposes the anterior femur. The proximal femur’s dense cortical bone makes it difficult to start a hole using a standard drill bit. The pointed soft tissue guides from large external fixation systems or a pointed drill bit can be used to prevent slipping off of the anterior cortex. The femoral artery lies 1 cm medial to the femur at the level of the lesser trochanter, so the surgeon must avoid slipping off the femur medially. Once the drill passes through the first cortex, it is removed from the drill bit to confirm radiographically that it will pass through the nail by the appearance of a perfect circle within the proximal interlocking hole. Small changes in the drill angle can be made to ensure correct passage through the interlocking hole. With a mallet, the drill bit can be gently tapped through the nail hole. The drill is then reattached to complete drilling through the posterior aspect of the proximal femur. Because of the proximity of the sciatic nerve, care should be taken to ensure that the drill is not advanced too far past the posterior cortex. Before removing the drill, the surgeon must reconfirm correct rotational alignment by flexing the hip and knee and assessing the hip’s internal and external rotation profile. It is compared with the normal internal and external rotation of the contralateral uninjured hip that was examined preoperatively. Screw length measurement can be confirmed with a frog-leg lateral or a true lateral view with flexing of the hip to clear the contralateral leg. A single proximal interlocking screw is all that is needed for most fractures. The usual length of the proximal interlocking screw is 25 to 35 mm. A second proximal interlocking screw may be selected for more proximal fracture patterns. A locking screwdriver should be used to avoid losing the screw in the proximal soft tissues. Alternatively, a suture can be tied around the head of the screw for retrieval if necessary. An internally rotated magnified view of the hip is obtained to critically reassess for the presence of a femoral neck fracture.
WOUND CLOSURE

- After wound irrigation, the knee fascial layer is closed with a 0 or 1-0 absorbable suture. The subcutaneous layer is then closed with 2-0 absorbable suture. The skin can then be closed with surgical staples.
- The interlocking screw incisions can be closed with 2-0 absorbable subcutaneous sutures and skin staples.
- Soft dressings are applied.
- Once the limb is undraped but before moving the patient off the operating table, it is critical to assess the achieved length and rotation compared to the contralateral limb. If any leg-length discrepancy or rotational deformity is appreciated, the limb should be reprepared, draped, and corrected by changing the proximal interlocking screw or screws.
- A repeat examination of knee stability is performed before leaving the operating room.

PEARLS AND PITFALLS

| Fracture reduction | The surgeon should request full relaxation with anesthesia to facilitate length restoration.
|                    | The surgeon should beware of the potential for shortening of the femur with retrograde insertion. Before placing the proximal interlocking screws, the surgeon should scrutinize the intraoperative radiographs of the fracture site to ensure that correct length has been obtained. Length may be regained by using the femoral distractor, or by using the guide to back-slap the nail after distal interlocking screw placement, or by manual traction. |
| Nail insertion: avoiding poor starting direction | The surgeon should ensure that the initial starting guidewire is centered in line with the femoral shaft on the AP and lateral images. Due to the overhang of the posterior condyles, there is a tendency to err too far posterior; because of the normal valgus of the distal end of the femur, there is a tendency to aim too medial, and a varus deformity can be created. |
| Nail insertion: avoiding slipping off | When starting to drill the initial guidewire, the surgeon should drop his or her hand slightly to prevent the wire from falling into the posterior cruciate ligament insertion; the hand is raised once the surgeon enters the cortex, so as to be in line with the femoral shaft. |
| Nail insertion: avoiding distal nail prominence | Before inserting the distal interlocking screws, the surgeon should confirm the subchondral position of the nail on the lateral intraoperative radiograph just deep to the apex of the line at Blumensaat (see Tech Fig. 2A). |
| Nail insertion: problems with proximal locking screws | The proximal femoral cortex is thick and strong. It is easy to strip proximal locking screws during their insertion. If difficulties are encountered on insertion, the surgeon should replace it with a new screw. This can help avoid significant issues if screw or nail removal is ever required. |
| Use of distal end cap | Some systems have a locking distal end cap that can lock the most distal screw in place; this is a useful feature for osteoporotic bone. End cap insertion can facilitate intramedullary nail removal if a reamed exchanged nailing for femoral delayed union or nonunion occurs. As with any nail insertion, if an end cap is used, it should be specifically mentioned in the operative note for review in the event of future screw or nail removal. |
| Avoiding distal interlocking screw prominence | Before removing the insertion jig, the distal femur is rotated under live fluoroscopy to evaluate the length of the distal interlocking screws. Screw length changes are made if necessary. Accurate measurement for locking screws minimizes postoperative hardware irritation. Off-axis screws are used when the option is available. |
| Associated injuries | The surgeon should always check the preoperative images and intraoperative C-arm images for ipsilateral fractures of the femoral neck. When using a hip screw side plate implant, the surgeon should try to overlap proximal hardware for improved mechanical properties. |
| Specific fracture patterns | Table 2 lists alternative techniques. |

POSTOPERATIVE CARE

- Physical therapy for active and passive knee range of motion may be started on the first postoperative day, as can ambulation, prescribed based on the fracture pattern and associated injuries.
- For most femoral shaft fractures, even those with comminution, weight bearing as tolerated can be safely initiated in the immediate postoperative period.
- Routine postoperative deep vein thrombosis prophylaxis, such as low-molecular-weight heparin, may be safely re-
alternative techniques

Two prospective, randomized trials comparing reamed antegrade and retrograde nailing of femoral shaft fractures showed no difference in knee pain or knee function at time of fracture union. As expected, early postoperative knee pain was more distal supracondylar femur fractures, which have taken longer to achieve union. The retrograde nailing technique appears to produce slightly higher malunion rates, with external rotation, shortening, and distal varus malalignment being the most common deformities. 

COMPPLICATIONS

The most common complications can often be prevented with meticulous surgical techniques. Paying close attention to the proper nail insertion starting point and ensuring that the distal portion of the nail remains subchondral are two key technical points to avoiding potential knee problems.

COMPLICATIONS

Twenty-four hours of antibiotic prophylaxis is standard for closed fractures. Patients with open fractures remain on antibiotics for 48 hours after the final intraoperative débridement has been performed.

OUTCOMES

The long-term effects of retrograde nailing on knee function are not known. Two prospective, randomized trials comparing reamed antegrade and retrograde nailing of femoral shaft fractures showed no difference in knee pain or knee function at time of fracture union. As expected, early postoperative knee pain was more distal in the retrograde femoral nailing groups, but by the time of union there was no significant difference between the two approaches. Fracture healing rates seem to be equivalent except in the more distal supracondylar femur fractures, which have taken longer to achieve union. The retrograde nailing technique appears to produce slightly higher malunion rates, with external rotation, shortening, and distal varus malalignment being the most common deformities. 

COMPLICATIONS

The most common complications can often be prevented with meticulous surgical techniques. Paying close attention to the proper nail insertion starting point and ensuring that the distal portion of the nail remains subchondral are two key technical points to avoiding potential knee problems.

Distal interlocking screw prominence is common, and a relatively high percentage of patients elect to have these removed as a secondary procedure. Malunions can be avoided when blocking screws are used judiciously for the more distal fracture patterns, and close attention is paid to ensure that the fracture reduction is first obtained and then maintained during the entire reaming process. Shortening and malrotation can be readily assessed at the end of the procedure and corrected immediately by revising placement of the proximal interlocking screw or screws. Selecting larger-diameter nails based on feedback of cortical chatter during reaming seems to improve union rates when the retrograde nailing technique is used.

REFERENCES

DEFINITION
- A femoral shaft fracture is any fracture of the femoral diaphysis from 5 cm below the lesser trochanter to within 6 to 8 cm of the distal femoral articular surface.
- Some fracture lines extend proximal or distal to the shaft and are therefore not considered shaft fractures.
- This description is mostly semantic, as the more important aspect of definition is understanding the “personality” of the fracture.
- Fractures whose essential element is diaphyseal with “extensions” into the outer regions are different than fractures whose essential element is subtrochanteric or supracondylar with extension into the diaphysis.
- In some circumstances there may be enough involvement of proximal or distal aspects that treatment must change.
- For the purposes of this chapter, we will focus on fractures that are amenable to antegrade nailing.10
- The Abbreviated Injury Scale (AIS) score for an isolated femoral shaft fracture is three, thus making the Injury Severity Score for an isolated femoral shaft fracture a nine.
- Open fractures are usually graded according to the Gustilo-Anderson classification, but one must keep in mind that this classification system was designed for the tibia, a subcutaneous bone. Thus, if absorbed energy is considered, theoretically, significantly more energy would be required to fracture a femur and disrupt the soft tissue envelope around a femur than around a tibia. Nonetheless, this system is widely employed in the femur for descriptive purposes.
- The fracture classification system previously used most commonly was the Winquist classification, but it has been modified and standardized with the AO/OTA classification, which is the recommended system.16,27

ANATOMY
- The femur is the longest bone in the body. It is subject to very high stresses in the proximal region because of the need to transition the forces of body weight via a lever arm (femoral neck) into more axial forces distally. As such, the subtrochanteric area is subject to very high stresses.14
- The femur has an anterior bow and is not a circular bone.
  - Anteriorly and laterally there are flattened surfaces, and posteriorly there is a taper that is confluent with the linea aspera.
  - The linea aspera is a very thick fascial structure and frequently remains in continuity but separates from the femur.
  - Entrapment of the linea aspera between the fracture ends may impede closed fracture reduction, especially with simple fracture patterns. The bone ends may need to be “unwound” to effect a reduction.
  - Both anterior and lateral bowing is important to recognize, especially if abnormal (e.g., metabolic bone disease).
  - The anterior bow has an average radius of curvature of about 120 cm.
- If there is excessive bowing, good preoperative planning is needed.
- Surgical options for such abnormal bowing include plate fixation or a controlled osteotomy to allow nail placement.16
- The endosteal diameter is important to recognize, especially with young or sclerotic bone.
- Normal aging and osteoporosis results in a biomechanical adaptation of enlarged inner diameter. Thus, elderly individuals may have a larger-diameter femoral shaft with a thinner cortex. As in other cylindrical tubes, the bending rigidity of the femur is roughly proportional to the radius to the fourth power.
- The vascular supply to the femur is from a nutrient artery off the second perforating branch of the profunda femoris, entering posteriorly along the linea aspera.
- Normally, periosteal branches supply the outer one quarter to one third of the cortex as the direction of blood flow is centripetally outward from the medulla to the cortex.
- Once fracture occurs, a reversal of blood flow occurs from the periosteal vessel, radially inward.
- The linea aspera protects many perforating periosteal vessels, except in severe fractures, and may help explain the high healing rate of femoral shaft fractures (about 95%).
- There are three thigh compartments: anterior, posterior, and medial.
- Thigh compartment syndrome may occur and generally involves the anterior compartment. Frequently, release of the anterior compartment will relieve pressure.
- The proximity of the gluteal compartment places it at risk as well. It should also be considered with compartment syndromes.

PATHOGENESIS
- Femoral shaft fractures are high-energy injuries in the young; in the elderly simple falls from ground level are sufficient to fracture the femur.
- Fracture patterns give clues to the mechanism.
  - For example, a simple transverse fracture with a butterfly fragment is due to a bending force (e.g., T-bone vehicle crash).
  - Spiral fracture patterns are usually due to torsional forces.
  - Indirect high-energy mechanisms, such as a fall from a height or motor vehicle crashes, will usually incur a significant initial deformity during the fracture process.
  - The active and passive recoil of the muscle soft tissue envelope will decrease the initial displacement. Thus, the extent of soft tissue injury can be difficult to appreciate.
  - Open fractures in this setting are usually “inside-out” injuries.
  - Direct mechanism fractures are from ballistic injuries, crush injuries, or other weapons (e.g., chainsaw, axe).
  - With these injuries, there may be less initial displacement of the fracture and soft tissues, but the amount of soft tissue injury can still be extensive.
In ballistic injuries, the shock and cavitation can result in extensive tissue necrosis.

In both mechanisms, it is important to recognize that the zone of tissue injury may extend well beyond the fracture site.

**NATURAL HISTORY**

In the early 20th century, the natural history of femur fractures was poor.

The mortality of wartime femur fracture before and during World War I was approximately 80%. Serendipitous use of a wheeled splint for transport off the battlefield resulted in a precipitous drop in the mortality rate (the Thomas splint was thus developed).

Because surgical techniques were primitive in those times, fears about infection and surgical complications resulted in most fractures being treated in traction.

The outcome was frequently a shortened, rotated, varus malunion of the femur.

Additional problems such as decubiti, venous thromboembolism, and pulmonary infections with prolonged bed rest resulted in high morbidity and mortality by today’s standards.

Kuntschner is considered the father of intramedullary nailing.

Kuntschner’s original technique was an open nailing, exposing the fracture site, and in the Western nations, poor surgical technique resulted in high rates of infection and nonunion.

As a result, this method of fracture care was abandoned until late into the 1970s.16

Kuntschner’s method was resurrected in the United States by early traumatologists, like S. Hansen and M. Chapman, who used Kuntschner’s newer technique of “closed” femoral nailing.

The success rate of femoral nailing using closed technique resulted in low morbidity and began a change in practice to what we perform today.

Early studies outlined the benefits of early reamed femoral nailing.

As survival of more traumatized patients increased, a subset of patients who may benefit from “subacute” nailing developed.

Later studies identified patients at risk (eg, pulmonary injury, incomplete resuscitation, and brain injury) who benefited from stabilization of life-threatening injuries before fixation.

This reflects the paradigm shift from early total care (ETC) to damage control orthopedics (DCO).1,19,22

While some have advocated plating in such cases, there has been no studies demonstrating the superiority of one method over the other in terms of patient survival.4

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Relevant history includes age, sex, mechanism of injury, associated injuries, loss of consciousness, weakness, paralysis, or loss of sensation.

Metabolic conditions and any musculoskeletal conditions should be elucidated if possible.

Patients should be evaluated according to the advanced trauma life support (ATLS) guidelines.

Particular attention should be given to hypotension, since femoral shaft fractures can be associated with up to 3 to 4 L of blood loss. While not solely responsible for hypotension, femur shaft fractures can be a contributory source.

The limb should be aligned and placed in a traction device, such as a Sager splint or a Thomas splint.

These devices should be removed and replaced with skeletal or limb traction because of the risk of skin problems in the perineal or ischial and ankle areas.

It is essential to inspect the affected limb for any open wounds, swelling, and ecchymosis (see Exam Table for Pelvis and Lower Extremity Trauma, page 1).

The extent of the open wound does not always correlate with the degree of soft tissue or fascial stripping due to the fracture.

Vascular evaluation should include manual palpation of the popliteal, posterior tibial, and dorsalis pedis pulses.

It is important to understand that a pulse is a pressure wave and can still be present in the absence of flow.

Alternatively, the absence of pulse does not always mean absence of flow.

Use of Doppler and examination of the contralateral limb are needed.

Hypotension with peripheral vasoconstriction may accompany such injuries.

The limb should be aligned before vascular examination.

Asymmetric or absent pulses warrant a measurement of the ankle-brachial index (ABI).

An ABI less than 0.9 is abnormal.

Arteriography should be considered to rule out vascular injury.

Neurologic evaluation includes motor and sensory function of the femoral and sciatic nerve.

The femoral nerve may be difficult to examine secondary to pain associated with the fracture.

Sciatic nerve function can be evaluated for both peroneal and tibial branches.

The peroneal branch is tested with ankle and toe dorsiflexion and sensation on the top of the foot.

Tibial branch function is tested with ankle and toe plantarflexion as well as sensation to the sole of the foot.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

The tenet of imaging a joint above and a joint below should be followed.

Good anteroposterior (AP) and lateral views of the hip, femur, and knee are required.

Such films can be obtained in the operating room but are essential in planning, since the presence of a femoral neck fracture or a fracture about the knee will greatly change the operative tactic.

Attempts should be made to get an internal-rotation AP view of the femoral neck. However, with current trauma algorithms, the commonality of the pelvic CT scan allows imaging of the femoral neck. The scan should be viewed before deciding on the surgical tactic.

If radiographs are normal but the clinical examination suggests injury (eg, unable to bear weight, pain out of proportion to injury), coronal MRI imaging may elucidate an occult fracture.

CT scanning in these situations may not be sensitive enough to find such fractures.

Occult femoral fractures may be hard to identify with preoperative radiographs.

Use of CT scans of the abdomen that go to the level of the femoral neck have been found to be sensitive enough to
identify such occult femoral neck fractures and should be done for most cases.  

DIFFERENTIAL DIAGNOSIS

- Other injuries may occur concomitantly with femur fractures, including pelvic fractures, acetabular fractures, femoral neck fractures, and ligamentous injuries to the knee.
  - If an effusion is present in the knee, the index of suspicion for a knee injury should be elevated.
  - Distal femur fracture may also occur but may not be radiographically evident, especially in osteoporotic bone.
  - In the absence of a reasonable mechanism, other causes for fracture such as metabolic bone disease or metastatic (or primary) fracture should be ruled out.

NONOPERATIVE MANAGEMENT

- Nonoperative management has typically been reserved for patients who are unfit for surgery, patients who are quadriplegic or paraplegic, patients in whom the benefits do not outweigh the risks, or other precluding factors (e.g., active infection).
  - Truly nondisplaced fractures in a compliant and able patient may also be treated nonoperatively.
  - Infants and young children may also be treated nonoperatively because of their ability to remodel.
  - Nonoperative management consists of bed rest and skeletal traction (either through the distal femur or proximal tibia) with 20 to 30 lb of weight.
  - Attention should be given to mechanical and pharmacologic venous thromboembolism prophylaxis if this treatment is considered.

SURGICAL MANAGEMENT

- Isolated femur fractures are not urgent. Appropriate evaluation and medical clearance should be performed. It is in the best interests of the patient and system to stabilize the patient expeditiously, but when appropriate resources are available (e.g., knowledgeable staff, anesthesia). It is not necessary to stabilize such fractures during off shifts unless indicated for other reasons (e.g., open fracture, polytrauma).
  - Patients with isolated femur fractures should have some form of traction, pain control, and deep vein thrombosis prophylaxis while awaiting surgical intervention.
  - Currently, statically locked femoral nailing with limited reaming is the standard of care.
    - The studies by Brumback et al determined that statically locked nails do not affect healing and avoid the problems of malrotation and shortening. Unreamed nails were proposed to limit effects of canal fill and the theoretical concern of infection. Neither concern was proven, and in fact small unreamed nails had the same problems as in the tibia: higher rates of nonunion. Currently, the “ream to fit” technique is used.  
    - In the multiply injured patient (Injury Severity Score of more than 18), with pulmonary compromise or head injury, fracture fixation should be delayed until suitably cleared for surgical intervention, and damage control methods with use of a temporary external fixator should be considered.
    - Recently, the reamer-irrigator-aspirator has been used to minimize the pressure-induced embolization from the marrow. As studies are ongoing, this method may reduce the risks in the multiply injured patients.
  - Open fractures can be safely nailed if a thorough débridement and irrigation is performed.
  - Absorbable antibiotic beads (calcium sulfate, not calcium phosphate, mixed with vancomycin or tobramycin) can be used at the time of definitive closure to provide local antibiotic delivery.
  - In severely contaminated fractures, a staged approach using temporary antibiotic beads (using polymethylmethacrylate mixed with vancomycin or tobramycin) and temporary external fixation, followed by nailing within 2 weeks (with or without use of absorbable beads), can be employed.
  - Conversion of external fixation to intramedullary nails can safely be performed within 2 to 4 weeks, as long as there is no indication of pin tract problems.
  - In such cases, the risk of infection is increased but acceptable in lieu of prolonged bed rest.
  - Because of deforming forces in proximal fractures, the proximal segment tends to flex and externally rotate.
    - Care should be taken to ensure that the posterior cortex of the proximal fragment is not inadvertently reamed away.
    - In distal fractures, the distal segment tends to flex at the knee (recurvatum of fracture).
    - With distal fractures, care should be taken to avoid varus or valgus reduction. This can occur because the opening of the medullary canal distally does not have intimate contact with the nail and does not “self-align.”
    - Transverse fractures may contain a segment of intact linea aspera that peels off the posterior aspect and may get entrapped in the fracture.
    - It can result in shortening that may be difficult to overcome without either “unwinding” the fracture or opening the fracture site.
  - In skeletally mature children, intramedullary nailing offers the same benefits as in adults.
    - Attention should be paid to adolescents with very valgus neck angles, as some have hypothesized that this can increase the risk of avascular necrosis of the femoral head. However, with modern implants, a trochanteric starting point may alleviate such concerns.
    - Skeletally immature children may still be considered for some form of intramedullary treatment after considering remaining growth, type of fracture, and benefits over other methods of treatment.

Preoperative Planning

- All films should be reviewed, with particular attention paid to the presence of an ipsilateral femoral shaft and neck fracture.
- The overall condition of the patient and any associated injuries should be contemplated before embarking on a surgical tactic.
- In the presence of pelvic or acetabular fracture, pregnancy, or obesity, one should consider a more elegant tactic, such as retrograde nailing, as opposed to antegrade nailing.
- If suitable, antegrade nailing in the supine position can be safely performed with proper positioning and knowledge.
- Several options have to be considered during preoperative planning. They include:
  - Table: fracture table or radiolucent
  - Position: supine or lateral
  - Entry point: piriformis or trochanteric
  - Type of nail: cephalomedullary or standard
  - Use of traction: skeletal, boot, or manual
Strong consideration should be given to checking fine cut CT scans to search for femoral neck fractures when possible. As part of the operative plan, the femoral neck should also be checked radiographically after fixation and prior to leaving the operating suite.

Positioning

Fracture table
- Standard fracture tables (eg, those used commonly for hip fractures) can be used for antegrade femoral nailing but are best used for supine position nailing.
- A large and well-padded perineal post should be used.
- Traction should be used sparingly and only when needed.
- The legs should be scissored to facilitate imaging and allow for appropriate countertraction. Placing the opposite leg in lithotomy position can allow rotation of the pelvis when traction is applied.
- The ability to image all aspects of the femur should be verified before preparing and draping (FIG 1A).

Radiolucent tables
- Newer tables allow free image intensifier access to the lower extremity.
- Some of the tables (Jackson table, OSI, California) also provide traction assemblies. These types of tables are suitable for multiple limb operations (FIG 1B).
- Our preferred method uses a radiolucent Jackson table with traction apparatus and lateral positioning (FIG 1C).

Supine position
- The supine position may be easier for surgeons to visualize anatomic relationships.
- It is more difficult to use supine positioning in obese patients.
- It may be the preferred position in patients with spinal cord injuries or severe chest injuries.
- It can be used with and without traction.
- If the supine (floppy) positioning on a radiolucent table is chosen, it helps to position the patient at the edge of the bed with a small bolster under the pelvis.
- Preparing and draping should include the posterior aspect of the gluteal area, since crossing the leg over will facilitate access to the piriformis.
- Even with the newer trochanteric entry technique and implants, the ability to manipulate the leg in adduction may be useful during the procedure (FIG 1D).

Lateral position
- The lateral position facilitates gaining an entry point, especially with a piriformis starting point in obese patients.
- It can be used with and without traction.
- When using the lateral position, the pelvis is rolled forward about 15 degrees to allow lateral imaging of the proximal femur.
- Care should be taken during positioning for proper padding and spinal precautions if occult spinal injury may be present.

**FIG 1** • A. Supine positioning on a fracture table with legs scissored. Slight obliquity using a bump under the sacrum helps with hip visualization. B. Supine position without traction on flat-top table. The ipsilateral hip should be close to the edge, and a bump under the sacrum will help with visualization. Standard lateral views of the hip for entry points can be used, but so can frog-leg laterals. C. Lateral position with traction. Skeletal traction in the proximal tibia or distal femur can be used. The perineal post is pictured here in the perineum, which is best for proximal fractures. In fact, little traction is usually needed and the post is frequently positioned under the apex of the fracture and used to overcome gravitational sagging. If traction will be needed, we have found that placing a blanket on the “down” leg and securing the contralateral thigh with a sling of tape coursing in a proximal and oblique fashion will resist moderate amounts of traction. D. Preparation and draping of the leg using a flat-top table without traction should include posterior sections of the buttocks. The leg can be crossed over to gain easier access to the piriformis starting point.
▪ Traction
  ▪ If traction is used, it frees an assistant and the length and rotation can be “set.”
  ▪ If manual traction is used, the length and rotation need to be checked before final interlocking.
  ▪ Skeletal traction can be via the proximal tibia or distal femur.
    ▪ The surgeon should be careful if there is any ligamentous instability of the knee, as suggested by a knee effusion or other sign of injury.
  ▪ In such cases, distal femoral traction can be used, and it can be prepared and draped into the operative field.
  ▪ Use of distal femoral traction can complicate distal interlocking because of the proximity of the traction apparatus with the interlocking site.
  ▪ Boot traction is a very common alternative.
  ▪ Unlike tibial or femoral skeletal traction, where the knee is slightly bent, boot traction uses a straight leg (FIG 1A).
  ▪ Care should be taken to avoid nerve traction injury (eg, avoid prolonged and excessive traction).
  ▪ Small perineal posts and long durations of traction have been shown to increase the risk of pudendal nerve injury.
  ▪ If traction is used, it should be first applied to determine the “reducibility” of the fracture. Then it should be reduced during prepping and applied as needed.
  ▪ Large and well padded perineal posts should be used whenever possible.6,15

SOFT TISSUE DISSECTION
▪ Whether using a cephalomedullary nail or piriformis fossa nail, the surgical approach is similar.
▪ The surgeon palpates the greater trochanter.
▪ For trochanteric entry, the skin incision is based about 4 to 10 cm above the trochanter in line with the femur.
  ▪ The tensor fascia is incised and the gluteus maximus is gently separated.
  ▪ The tendinous insertion of the gluteus medius is frequently more distal, and this tendon can be gently spread to identify a bursal area just below the medius and above the minimus.
▪ For piriformis entry, the incision is made about a hand-breadth along the line between the trochanter and the posterior superior iliac spine.
▪ Once the gluteus maximus is gently separated, the access to the piriformis is posterior to the medius.
▪ The piriformis fossa can be easily palpated as a “dimpled ledge” behind the trochanter. This anatomic feature is used during the percutaneous approach for proprioceptive feedback during pin placement.

TROCHANTERIC AND PIRIFORMIS FOSSA ENTRY
▪ After soft tissue dissection, the tip of the greater trochanter is palpated. The piriformis fossa is palpated medially.
▪ The ideal starting point for a piriformis fossa nail is in the fossa along the medial upslope of the greater trochanter, since this is most in line with the shaft.
  ▪ This point may vary between patients and should be confirmed with intraoperative fluoroscopy.
▪ The surgeon can have an assistant adduct the extremity to aid in exposing this spot (TECH FIG 1A).
▪ Once the starting point is identified by palpation and confirmed with fluoroscopy, the cortex is penetrated with either an awl or a threaded Kirschner wire.
▪ Every effort should be given to establishing an accurate starting point (ie, one that is in line with the femoral shaft).

TECH FIG 1 • A. AP image of the correct position of a guide pin for piriformis entry. B. Lateral image of piriformis starting point. The pin need only start in the piriformis; it will frequently course anterior, and care should be taken not to penetrate the anterior cortex. The rigid reamer need only open the top of the bone for access to medullary canal.
The percutaneous method of nailing uses cutaneous landmarks to identify the ideal entry site, which is usually about one full handbreadth (8 cm) from the posterior corner of the trochanter towards the posterior superior iliac spine (TECH FIG 2A).

The incision is a stab wound.

A guide pin is advanced to the trochanteric bursa (TECH FIG 2B).

The pin is "rolled" off the posterior slope of the trochanter and then advanced distally and anteriorly (TECH FIG 2C, D).

A very distinct resistance is felt, as if on a pedestal or ledge of bone. The tip of the pin provides proprioceptive feedback when this occurs, and it can be felt that there are structures anterior and medially, which constitute the "walls" of the fossa.

In these cases, preparing under the buttock and accessing from a more posterior approach may allow access to the fossa.

The lateral positioning allows the easiest access, with very few problems. In fact, nailing can be performed percutaneously (described below) with little problem when using the lateral position.
TECH FIG 2 • (continued) E. The rigid reamer advances over the pin to enter the proximal femur. Use of irrigation will help prevent soft tissue catching. F. Insertion of the nail over the guidewire. With use of a bent guidewire and “ream-to-fit” technique, the likelihood of an incarcerated reamer is very low, and exchange of the guidewire with a chest tube is not needed (unless a ball-tip guidewire is used). G. Intraoperative photo of final wounds. H. Entry site wounds are usually about 1.5 cm.

- At this point image verification is performed.
  - If the pin is not coaxial with the femur, what is most important is that the tip of the pin is centered.
  - The pin is advanced to engage the cortex, and then a 9- to 12-mm rigid reamer is used to open the proximal femoral cortex (TECH FIG 2E).
  - This reamer need only be advanced enough to open the cortex and provide access to medullary contents. Care should be taken not to ream too deeply and perforate the cortex of the proximal femur anteriorly (see Tech Fig 1).
- Once this step is accomplished, the remainder of the procedure can be done with standard methods, and instruments are passed via the keyhole skin incision (TECH FIG 2F–H).

TROCHANTERIC ENTRY, GUIDEWIRE PLACEMENT, AND FRACTURE REDUCTION

- After soft tissue dissection (as described previously), the surgeon palpates the tip of the greater trochanter and its anteroposterior dimensions.
- Because of the inherent anatomy of the proximal femur, the ideal starting spot for a trochanteric entry nail is at the tip of the greater trochanter (mediolateral) and the junction of the anterior one third and posterior two thirds of the greater trochanter.
- This spot may vary from person to person, but the correct starting point is one that is in line with the femoral shaft.
- Once the correct starting spot is identified, the outer cortex is penetrated with either an awl or a pointed guidewire (TECH FIG 3A).
- In this method, because the abductor mechanism is being split, soft tissue protection is important.
- After the starting point is identified, a guidewire is placed into the proximal femur and passed down the canal.
- Forceful and jerking motions can be avoided by firmly twisting the guidewire through the cancellous bone.
- A gentle J bend at the distal 1 cm of the wire allows the wire to be “bounced” off cortices and to be “steered” in metaphyseal areas (TECH FIG 3B).
- The proprioceptive feedback of a wire passing along the medullary canal is similar to the sensation of pushing a stick on a sidewalk.
TECH FIG 3 • A. The entry point for the trochanter is usually on the anterior one-third junction. B. Bent straight guidewire. This helps to “steer” the wire in metaphyseal bone and will prevent reamer heads from disengaging (relevant only in modular designs). C. The “wand.” It is available on some sets, or can be performed with some extraction rods. It is placed over the guidewire into the proximal segment, down to the level of the lesser trochanter. It can manipulate the proximal fragment to aim it into the distal segment, after which the guidewire is advanced into the distal fragment. This is much more desirable than struggling with manual methods. D. F bar. This can be placed around the thigh to effect the desired translation. In out-of-plane deformities, the bar can find the “ideal” orientation and effect a reduction. E. The joystick method. Small terminally threaded wires can be drilled into the cortex of each segment and used to manipulate the fragments into reduction. Small external fixator pins can also be used and have been previously described. F. Intraoperative image of guidewire passed across fracture.

- If the fracture is not reduced sufficiently to easily pass the wire across, there are several techniques available to facilitate reduction and wire passing.
- Some nail systems provide a cannulated rod that is placed over the wire and passed into the proximal femur. This rigid wire holder functions as a wand to manipulate the proximal fragment as the wire approaches the fracture so that it can easily be passed across (TECH FIG 3C).
- An F or H bar, a crutch, or both can also be useful to manipulate the proximal and distal fragments (TECH FIG 3D).
Sometimes the fracture cannot be perfectly reduced, but enough provisional alignment can be established to pass the guidewire. If the fracture is unstable and difficult to reduce after numerous attempts, a small incision can be made along the lateral thigh over the fracture and the fracture can be digitally reduced and provisionally aligned. In some cases, the incision can be lengthened to allow placement of “lobster claw”-type clamps.

Other methods include the use of unicortical “joystick” half-pins from an external fixator set (usually a 5-mm half-pin). Alternatively, 3-mm threaded guide pins can also be used (TECH FIG 3E). The guidewire position in the distal segment is confirmed with intraoperative fluoroscopy. The guidewire should be passed down to the distal femur physeal scar and should be center-center on both the AP and lateral views.

MEASUREMENT AND REAMING

Once the guidewire has been placed, the length of the nail is measured either with a measuring device (usually supplied by the intramedullary nail system) or by using a guidewire of the same length. Placing the second wire at the entry site and measuring what is not overlapping with the inserted wire provides nail length. Before measuring, the surgeon confirms the proximal position of the ruler on the greater trochanter. The surgeon should make sure that there is no soft tissue between the ruler and the top of the greater trochanter, as this can artificially increase the length of the nail chosen. Average nail lengths range from 38 to 42 cm. Using the radiographs of the femur, the surgeon can estimate the beginning reamer size. With “tight” canals, reaming should begin with lower sizes, and sequential reaming can begin starting with the lowest size available (usually 8 or 9 mm). When starting to ream, the surgeon should pay particular attention to keep the reamer medial in the proximal femur to prevent reaming out the posterior or lateral cortex.

If the reamer does not pass easily, the surgeon should check its position with fluoroscopy since the reamer may be hitting cortical bone (usually anteriorly). Reaming can be increased by 1.0-mm increments until distinct “chatter” is encountered, after which it should increase in 0.5-mm increments.

Once endosteal “chatter” is encountered, reaming should continue for another 1.0 to 2.0 mm, and a nail diameter of 1.0 to 1.5 mm smaller than the largest diameter reamed should be used. With modern nail designs, most male patients can be treated with 11- to 13-mm nails and most females with 10- to 12-mm nails. Care should be taken when there is a tendency for a deforming force to allow for “eccentric” reaming (eg, proximal fractures). In these cases, without attention, eccentric reaming can remove cortical bone and create defects that result in deformity or a nail outside the bone.

NAIL PLACEMENT

If a ball-tipped wire is used, the surgeon should confirm that it can be pulled through the nail or exchanged for a smooth-tip wire. After the nail has been inserted, its position is checked distally, at the fracture site, and proximally near its insertion site. The surgeon ensures that the nail is not too proud above the greater trochanter and fossa. If the fracture site is distracted, traction should be reduced or adjusted to effect a satisfactory reduction.

Length and rotation need to be reconfirmed before interlocking. Several methods can be used.12,13,24,25

Cortical characteristics

- The femur diameter is not symmetric. Variances in cortical thickness can be used to estimate rotation.
- Fracture lines can be used to estimate correct rotation.

Radiographic methods

- One method checks the true hip lateral with the distal femoral lateral in the intact contralateral femur. The measured difference is mirrored in the fractured side.
- In cases of comminution or bilateral fractures, another method can be used to determine or set the rotation. A true lateral of the distal femur is obtained, and the intensifier is then moved orthogonal to this position, and the proximal femur is visualized to obtain a profile of the lesser trochanter. The images are saved for reference, and mirrored on the fractured side, or contralateral side if bilateral.

Surprisingly, rotational deformities appear to be well tolerated, with an average of 28% of patients having a deformity of more than 15 degrees.

Internal rotation is tolerated better than external rotation.

In all cases, a clinical examination of rotation of both legs with the pelvis supine and the hip flexed to 90 degrees can be used to estimate symmetry. Unless the patient is in extremis, all nails should be statically locked.

The order of interlocking should be considered.

In axially stable cases, the distal segment should be interlocked, and compression applied by back-slapping the nail.

In unstable cases, traction and alignment should be maintained until interlocking is complete. Usually distal interlocking precedes proximal interlocking.5,28
**PROXIMAL INTERLOCKING SCREW PLACEMENT**

- There are guides with each system that allow placement of proximal screws. In general, at least one screw should be placed.
- Unless the fracture is stable, the static screw hole should be used, and the hole closest to the fracture is preferred.

**DISTAL INTERLOCKING SCREW PLACEMENT**

- Distal screw placement is usually done with a freehand technique. This can be one of the most challenging parts of the case for some surgeons and the easiest for others.
- In general, setup and image positioning can greatly facilitate this part of the procedure.
- Using the concentric circle concept, the image intensifier or the leg is rotated to obtain a perfect circle.
- If the image is oval or shaped like an eye, the image intensifier is not perpendicular to the axis of the nail, or in other words, parallel or co-axial with the axis of the screw hole.
- The goal is to align the axis of the image intensifier with that of the screw hole. Getting perfect circles is the first critical step.

  - In **TECHNIQUES FIGURE 4A**, the image intensifier is not aligned in the coronal plane (varus or valgus to the femoral nail).
  - In **TECHNIQUES FIGURE 4B**, the image intensifier is not aligned in the axial–transverse plane (rotationally to the nail).

- In **TECHNIQUES FIGURE 4C**, both screw holes in the nail line up, giving the “perfect circle” wherein the image intensifier is co-linear to the axis of the screw hole in the nail.

  - Next, a drill or scalpel is used to determine the cutaneous location for an incision, which should go through the fascia and to bone.
  - A drill is centered over the hole and held securely (**TECH FIG 4D**).
  - At this point there are two options: the drill can be gently tapped to engage the near cortex, or it can be drilled.
  - The axis of the drill bit should be aligned with the center of the image intensifier (which is parallel to that of the hole). Thus, if the drill tip is centered over the hole and aligned with the center of the intensifier, it should be co-axial with the axis of the hole.

**TECH FIG 4** • **A.** The perfect circle method for freehand interlocking. If the image appears as two circles overlapped, the shape of an 8 will appear. The central area is elliptical and indicates that the image intensifier axis is not collinear with the axis of the screw holes. The appropriate corrective direction is parallel to the short axis of the central ellipse (or perpendicular to the long axis). In this case, the correction would be in the coronal plane (proximal-to-distal). **B.** In this situation, the rotation of the image does not match. It will need to be corrected along the path of the C. **C.** The image of a perfect circle. (continued)
Chapter 10  ANTEROGRADE INTRAMEDULLARY NAILING OF THE FEMUR

TECHNIQUES

~3 nail diameters
36-40 mm
~5.5 nail diameters
65 mm

D. The drill point should be in the middle of the circle. Then the axis of the drill can be made collinear with that of the image intensifier. E. The drill can pass anterior or posterior to the nail and “feel” pretty good. Care should be taken to make sure the drill point does not drift during this motion. Proprioceptive feedback will frequently indicate when the drill passes through the nail and the contralateral cortex. If the drill “kicks” in one direction (anterior or posterior) it may have missed the nail. If it is not aligned in the coronal plane, it may hit the nail. It is important to verify all implant positions before leaving the operating room. F. A method of measuring using the nail as a “yardstick.” If the diameter of the nail is known, then the diameter of the bone at the level of the interlocking hole can be estimated by seeing how many multiples of the nail will fit in that segment. With some practice the accuracy of this technique is impressive: we estimate our accuracy to exceed 90% using this technique.

- Once the drill is into the bone and advanced, fluoroscopic verification should be obtained, after which the drill is advanced to the far cortex.
- If the drill bit “kicks” or jerks into a different direction or cannot be advanced, it is likely that it either glanced off the nail (missed the hole anteriorly or posteriorly) or is hitting the nail (proximally or distally) (TECH FIG 4E).

Measurement

- The drill can be removed and measured with a depth gauge or in many systems read directly from the drill guide.
- An alternate method, which we have used with surprising accuracy, is to use the known diameter of the nail as a legend.
- Comparing the width of the femoral canal at the level of the screw hole with that of the nail and estimating the number of nail widths in that segment allows for an estimate of the screw length.
- With a little practice, this method is fairly reliable, especially considering that many companies provide screws only in 5-mm increments (TECH FIG 4F).

PEARLS AND PITFALLS

Preoperative
- Correct position and traction are chosen based on patient size and assistant availability.

Intraoperative
- After nail insertion the surgeon should always check limb rotation, limb length, and the femoral neck (iatrogenic fracture).
- Care should be taken when fracture lines are within 6 to 8 cm of the interlocking sites. In these cases, higher stresses can result in complications of the nail or delayed healing, and weight bearing can be initiated with radiographic initiation of healing (callus).
- Patients should be provided with physiotherapy for range of motion of the knee and hip and encouraged to exercise the abductors as well.
- Deep vein thrombosis prophylaxis should be considered for all patients, unless contraindicated.

POSTOPERATIVE CARE

- Postoperative radiographs should be obtained to check fracture alignment, rotation, and nail and screw placement as well as to ensure the integrity of the femoral neck.
- A clinical examination for rotation of the hip and a thorough knee examination are needed to rule out occult knee injury.
- Most femoral fractures, irrespective of comminution, can be allowed weight bearing as tolerated.
OUTCOMES

- The femur can be expected to heal in about 95% of cases, with an infection rate of about 1% (FIGS 2 AND 3).
- Knee motion should return to normal about 12 weeks postoperatively, but may be limited in head-injured or polytrauma patients owing to heterotopic bone formation or lack of early motion.\(^{18}\)
- While healing rates are good, there is almost always an objective deficit in outcomes, which may or may not be clinically relevant.
  - Objective examination can reveal deficits in endurance and strength, weather-related symptoms, or residual hip, thigh, and knee pain.
  - Much like tibial nailing, the causes of such symptoms have not been well elucidated.

COMPLICATIONS

- Iatrogenic femoral neck fracture
- Up to 15 degrees of rotational malalignment can be well tolerated, but greater than 15 degrees should be corrected.
  - Rotational deformity can be prevented by paying close attention to cortical thickness, since the femur is not perfectly cylindrical and cortical thickness varies.
  - Angular malalignment can be defined as greater than 5 degrees of angulation in coronal or sagittal planes.
  - The overall rate of malalignment is 7% to 11%, with most angular deformities occurring at the proximal and distal thirds of the femur.\(^{16}\)

- Up to 1.5 cm of leg-length discrepancy may be well tolerated.
  - Beyond 2 cm, many patients will eventually complain of symptoms of malalignment (eg, back, knee, or ankle pain).
    - While symptoms should resolve with simple shoe modifications, most patients are not able to maintain compliance.
- Infection is an infrequent but devastating complication. It can be treated by several methods.
  - If the infection is early and fixation is stable, local and systemic antibiotic treatment with nail retention may be considered.
  - If the infection is extensive, a staged procedure should be considered with use of a temporary custom-fabricated antibiotic-impregnated intramedullary device, possibly an external fixator, and a course of intravenous antibiotics.
  - If the infection is delayed and the fracture is partially healed, one can also consider an exchange nail with reaming and placement of a nail of greater size (usually 2 mm).
- Most femur fractures should be considered for a combination of mechanical and pharmacologic prophylaxis against deep vein thrombosis.
- Fat emboli are a rare occurrence.
  - Studies on the reamer-irrigator-aspirator are pending. This device may prevent fat emboli.
- Decreased hip function and muscle weakness of the hip abductors and external rotators, along with trochanteric pain, thigh pain, and limp, may occur.
  - There is a small but definite occurrence of hip dysfunction with femur fractures.
While it still occurs with even retrograde nailing, the incidence seems to be greater with antegrade nails, but recent data using a trochanteric starting point appear promising.

Further and more definitive studies are warranted. There is no superior method.

Heterotopic ossification may occur in 9% to 60% of patients, with the most commonly associated factor being head injury.

Failed hardware or refracture usually indicates a nonunion. In some cases, fracture of locking screws serves to “autodynamize” the fracture and healing ensues.

There is no need for hardware removal or additional surgery if the fracture heals with minimal deformity.

Stretch injury of the sciatic nerve due to prolonged traction during intramedullary nailing can be avoided with judicious use of traction.

Treatment consists of expectant and supportive treatments.

Pudendal nerve palsy (if intramedullary nailing is performed on a fracture table) can occur when excessive traction and a small perineal post are used.

Most femur fractures can be brought to length easily, and traction should be limited to the time of reduction and nail passage and interlocking.

Use of a large, well-padded perineal post, judicious traction, or a femoral distractor can avoid this problem.

Compartment syndrome of the thigh (especially in intubated, polytrauma victims) may occur, especially with crush injuries or prolonged hypotension.

Clinical signs should be used to dictate treatment, and release of the anterior compartment is generally sufficient.

If compartment pressures are to be monitored, threshold pressure is 30 or 40 mm Hg or one that is based on the patient’s diastolic blood pressure (within 30 mm Hg).

REFERENCES

DEFINITION
- Distal femur fractures are difficult, complex injuries that can result in devastating outcomes.
- The distal part of the femur is considered the most distal 9 to 15 cm of the femur and can involve the articular surface. The intra-articular injury can vary from a simple split to extensive comminution.
- Articular involvement can lead to posttraumatic arthritis.
- These fractures constitute 4% to 7% of all femur fractures.
- If the hip is excluded, they represent nearly one third of all femur fractures.
- There is a bimodal distribution defined by the mechanism of injury (see below).

ANATOMY
- The supracondylar area of the femur is the zone between the femoral condyles and the metaphyseal–diaphyseal junction.
- The metaphyseal bone has some important structural characteristics.
  - The predominant bone is cancellous.
  - The cortices are especially thin.
  - There is a wide intramedullary canal.
- It is also important to understand the unique bony architecture of the distal femur (FIG 1).
  - It is trapezoidal in shape, and hence the posterior aspect is wider than the anterior aspect. There is a gradual decrease by 25% in the width from posterior to anterior.
  - The medial femoral condyle has a larger anterior-to-posterior dimension than the lateral side and extends farther distally.
  - The shaft is in line with the anterior half of the distal femoral condyles.
- The normal mechanical and anatomic axes of the lower limb must be understood so that the alignment of the limb can be re-established (FIG 2).
  - The mechanical femoral axis, which is from the center of the femoral head to the center of the knee, is 3 degrees off the vertical. The mechanical axis of the entire limb continues to the center of the ankle.
  - The anatomic femoral axis differs from the mechanical femoral axis in that there is 9 degrees of valgus at the knee. This results in an anatomic femoral axis of the lateral distal femur of 81 degrees or an anatomic femoral axis of the medial distal femur of 99 degrees.
  - The mechanical and anatomic axes of the tibia are for practical purposes identical, going from the center of the knee to the center of the ankle.
- The treatment of distal femur fractures can be complicated by the various muscle attachments, which can impede or hamper proper fracture reduction.
  - The quadriceps and hamstrings result in fracture shortening; thus, excellent muscle paralysis must be obtained for proper reduction.
  - The medial and lateral gastrocnemius results in posterior angulation and displacement of the distal segment. The distal femur “extends,” resulting in an apex posterior deformity. If an intercondylar extension is present, rotational deformities of the individual condyles can occur (FIG 3A,B).
  - The adductors, specifically the adductor magnus, which inserts onto the adductor tubercle of the medial femoral condyle, can lead to a varus deformity of the distal segment (FIG 3C).
- The neurovascular structures about the knee are at risk when an injury of the distal femur occurs.
Chapter 11  ORIF OF THE DISTAL FEMUR

Anatomic axis
Knee joint axis
Mechanical axis
Vertical axis

![Diagram showing mechanical and anatomic axes of the lower extremity; the 9 degrees of valgus at the knee is noted.]

- Low-energy injuries usually occur in the elderly patient who falls from a standing height. The axial loading is accompanied by either varus or valgus with or without rotation. The osteoporotic bone in these individuals leads to fracture. The fracture pattern can vary from the most simple extra-articular type to the most complex intra-articular injury. Owing to the gastrocnemius complex, an apex posterior deformity of the condyles occurs as the fragments are flexed because of the muscle attachment.

NATURAL HISTORY
- Fractures of the distal femur that have intra-articular displacement can lead to severe posttraumatic arthritis if left untreated.
- Operative treatment has led to a 32% decrease in poor outcomes.9

PATIENT HISTORY AND PHYSICAL FINDINGS
- Direct physical examination of the knee with a distal femur fracture is limited primarily because of pain and the obvious nature of the injury.
  - The patient presents with a swollen and tender knee after either a fall or some high-energy trauma (motor vehicle or motorcycle accident).
  - A large hemarthrosis is present.
  - Any attempts at range of motion result in severe pain, and significant crepitus is usually noted with palpation.
  - If there is concern for an open knee joint, the joint can be injected after a sterile preparation to see whether the knee joint communicates with any wound.
  - The physical examination is directed primarily at ascertaining the neurovascular status of the lower limb and determining whether any associated injuries exist, especially the hip (see Exam Table for Pelvis and Lower Extremity Trauma, pages 1 and 2).
  - If there are any small wounds or tenting of the skin anteriorly, the fracture should be considered as being open.
  - It is important to check for pulses.
    - If diminished or absent, pulses should be assessed with Doppler.
    - The ankle-brachial indices should be obtained if there is a concern for arterial injury.
    - Any side-to-side difference or value less than 0.9 warrants an arteriogram.
  - Nerve function should be checked. Sensation and both active dorsiflexion and plantarflexion must be assessed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The initial imaging study is always plain radiographs. Anteroposterior (AP) and lateral radiographs of the knee should be obtained initially.
  - Traction films should be obtained if there is severe comminution of either the metaphysis or articular surface. This aids in the preoperative planning.
  - Dedicated knee films should always be obtained in the assessment of distal femur fractures. Additionally, the entire femur, to include the hip and knee, should be imaged to look for possible extension and associated injuries and to allow for preoperative planning (FIG 4).
  - In cases of severe comminution, radiographs of the contralateral knee can aid in preoperative planning as well.
FIG 3 • A. Patient with a grade IIIA open distal femur with extruded fragment; the "extension" of the femoral condyles is outlined.
B. Patient with a distal femur fracture with intercondylar extension showing the subtle rotational deformities of the individual condyles.
C. The muscle forces are shown on the distal femur, as is the femoral artery and vein entering the canal of Hunter (arrow). The adductor magnus inserts on the adductor tubercle, leading to a varus deformity of the distal segment.
D. A lateral image of the same patient with the popliteal artery and tibial nerve drawn in to show the relative proximity to the fracture ends.
FIG 4 • A–C. Patient with a spiral distal-third femur fracture that appears to be extra-articular. A. In the AP radiograph, the knee is not fully visualized. B. A dedicated knee AP radiograph shows the spiral distal-third femur fracture. Note the intra-articular injury and the gap at the fracture (arrows). C. Lateral view of the knee. Again note the coronal fracture of the medial femoral condyle (type B3). D–F. Plain radiographs of a patient with a grade II open distal femur fracture. G,H. Patient with a closed femur fracture that was initially thought to be extra-articular.
A dedicated CT scan is an important adjunct to the preoperative planning when there is articular involvement (FIG 5). Generally, extra-articular distal femur fractures do not require a CT scan. However, it has been shown that coronal fractures may be missed on plain films, and thus there is a low threshold for obtaining a CT scan for fractures of the distal femur.4

If the fracture pattern warrants a temporary bridging external fixator, it is best to obtain the CT scan after placement of such a fixator for better definition.

![FIG 5 • A. Axial CT image of patient in Figure 4A–C confirming the type B3 fracture of the medial femoral condyle. B. Axial CT image of the patient in Figure 4D–F. C–E. CT images of the patient in Figure 4G,H show the nondisplaced intercondylar split as well as the low lateral fracture line and extensive posterior metaphyseal comminution (type C2).]

Coronal and sagittal reconstructions should be requested. Three-dimensional images can be created from most CT scans. This can also aid in the preoperative planning (FIG 6A,B).

Subtle sagittal-plane rotational malalignment between condyles can be assessed (FIG 6C).

If associated soft tissue injury is suspected, such as ligamentous tears or tendon ruptures, then MRI may be indicated. Routine use of MRI, however, is not needed.

![FIG 6 • AP (A) and lateral (B) views of a 3D CT reconstruction of the patient in Figure 3B with a distal femur fracture. The fracture is well defined. C. An oblique 3D CT reconstruction view showing the same patient and the rotational malalignment between condyles.]
DIFFERENTIAL DIAGNOSIS
- Proximal tibia fracture
- Femoral shaft fracture
- Septic knee
- Patella fracture
- Anterior cruciate ligament rupture
- Knee dislocation

NONOPERATIVE MANAGEMENT
- There are few relative indications for nonoperative management of distal femur fractures:
  - Poor overall medical condition
    - Patient has severe comorbidities and is too sick for surgery.
    - Patient has extremely poor bone stock.
  - Spinal cord injury (paraplegia or quadriplegia)
  - Some special situations may warrant nonoperative care on case-by-case basis.
    - Nondisplaced or minimally displaced fracture
    - Select gunshot wounds with incomplete fractures
    - Extra-articular and stable
    - Unreconstructable
    - Lack of experience by the available surgeon or lack of equipment or appropriate facility to adequately treat the injury. Transfer is indicated in these situations; otherwise, nonoperative treatment may be the only option.
- There are several methods for nonoperative treatment.
  - Skeletal traction
  - Cast bracing
  - Knee immobilizer
  - Long-leg cast
- There are acceptable limits for nonoperative management:
  - 7 degrees of varus or valgus
  - 10 degrees of anterior or posterior angulation. A flexion deformity is less well tolerated than an extension deformity.
  - Up to 1 to 1.5 cm of shortening
  - 2 to 3 mm of stepoff at the joint surface

SURGICAL MANAGEMENT
- The goal of any treatment, nonoperative or operative, is to maintain or restore the congruity of the articular surface and restore the length and alignment of the femur and subsequently the limb.
- Once surgery is deemed appropriate for the patient and the particular injury, the surgical technique options available are determined by the particular fracture pattern.
- Distal femur fractures have been classified several ways.
  - The AO/OTA classification is probably the most widely accepted classification system and allows some guidance on which techniques are best (FIG 7, Table 1).
- Treatment also must be determined based on factors other than the classification alone.
  - The degree of comminution and injury to both the articular surface and bone
  - The amount of fracture displacement
  - The soft tissue injury
  - Associated injuries, other fractures, and injury to neurovascular structures
  - Patient’s overall condition and injury to other organ systems. This may affect the timing of surgery or the positioning of the patient.

</table>
There are several principles for the surgical management of distal femur fractures:

- The articular surface must be reduced anatomically, which usually requires direct visualization through an open exposure (arthrotomy). Simple intra-articular splits may be treated with closed reduction and percutaneous fixation.
- The extra-articular injury should be dealt with using indirect reduction techniques as much as possible to maintain a biologic soft tissue envelope. Avoidance of stripping of the tissues, especially on the medial side, is ideal.
- The surgeon must re-establish the length, rotation, and alignment of the femur and the limb.
- The soft tissue injury and bone quality may dictate treatment decisions.

**Fixation Choices**

- **External fixation**
  - A temporary bridging external fixator across the knee joint can be used if temporary stabilization is required before definitive fixation. This is usually the case where definitive open reduction and internal fixation is planned. This could be in cases where the soft tissues prevent immediate fixation.
  - Definitive management with bridging or nonbridging external fixation can be used for unreconstructable joints, very severe soft tissue injuries, or severe osteopenia.

- **Intramedullary nailing**
  - This can be performed fairly acutely; temporary bridging external fixation is not necessary.
  - Antegrade intramedullary nailing has been described and can be used for distal fractures with a large enough distal segment to allow for two locking screws. Malalignment has been a problem, as has adequate fixation.¹,²
  - Retrograde intramedullary nailing can be used in the following cases:
    - All extra-articular type A fractures greater than 4 cm from the joint. This minimal length of the distal femur allows for multiplanar interlocking in the distal fragment.
    - Type C1 or C2 fractures where the articular fracture can be anatomically reduced closed or with limited exposure. Percutaneous screws are used for the articular injury.
    - Periprosthetic fractures around a total knee arthroplasty with an “open box” femoral component.

- **Plate fixation**
  - Open reduction and internal fixation with plates can be used for all types A and C fractures but is ideal for the following injuries:
    - Very distal type A fractures within 4 cm of the knee joint
    - All articular type C fractures, but always for C3 types
    - Periprosthetic fractures about a “closed box” femoral component of a total knee arthroplasty
    - The partial articular type B1 or B2 if an antiglide plate is needed
  - Plate options (preferred to least preferred; fixed-angle devices preferred)
    - Fixed-angle locking plates (percutaneous jigs are advantageous and allow for minimally invasive techniques)
    - 95-degree condylar screw
    - 95-degree blade plate
    - Nonlocking plates with or without medial support (medial plate or external fixation)

- **Limited internal fixation**
  - Limited fixation with screws only can be used for partial articular type B, especially type B3.
  - The amount of open reduction required depends on the adequacy of closed reduction techniques and obtaining an anatomic reduction of the joint surface.
  - Headless screws are useful for type B3 fractures in which the screws have to penetrate the joint surface (FIG 8).
  - Countersinking the screw heads can also be performed.

**Preoperative Planning**

- Surgical timing can be affected by:
  - Soft tissue issues
  - Medical condition of the patient
  - Adequacy of available operative team
  - Availability of implants
- The approach must take the following issues into consideration:
  - The ability to incorporate lacerations in open fractures into the incision (FIG 9) can be useful and should be considered. However, this is not always necessary or possible.
Soft tissue dissection should be limited.

Adequate exposure is important to anatomically restore the articular surface.

Restoration of limb “anatomy” must be accomplished and allow early range of motion.

Stable internal fixation and length and sizes of implants should be templated. Radiographs of the injury can be templated with implant templates to ensure that proper lengths are available. A tentative plan of the fixation construct can be drawn on the image. Additionally, “preop planning” of the operating room should be performed; this includes a discussion with the operative team about the positioning and equipment needed for the procedure.

The need for bone grafting should be assessed (eg, iliac crest bone graft versus allograft or bone graft substitutes).

Fracture fragments and the anticipated fixation construct should be templated.

The surgeon should check for coronal plane fractures of the condyles (also known as Hoffa fragments) (see Figs 4C and 5).

Associated injuries may affect the treatment options.

An ipsilateral hip or more proximal shaft fracture may alter the implant choice. A longer plate may be needed to address both injuries, or consideration to overlap implants may be warranted to avoid a stress riser.

An associated proximal tibia fracture may alter the approach used. A more lateral incision incorporating a lazy S incision for the proximal tibia injury may be required.

### Positioning

- A radiolucent table should be used to allow adequate visualization with a C-arm.
- The patient is placed supine with a hip bump.
- The rotation of the proximal segment of the fracture (hip) should be aligned before patient preparation.
  - Using the C-arm, the profile of the lesser trochanter with the corresponding knee (patella) straight up is determined on the uninjured side (FIG 10A, B).
  - The injured hip is imaged and internally rotated by the hip bump so that duplication of the profile of the normal side is achieved. The size of the bump may be adjusted as needed for the amount of rotation required.
- The injured knee is placed in the patella-up position to confirm rotation.
- This technique is helpful in comminuted metaphyseal fractures where the rotation is difficult to assess or in cases where the metaphyseal component will not be directly visualized.
- Even though the distal segment is not in “fixed” rotation, this technique is useful to minimize the chance of a malrotation during definitive fixation.
- A sterile tourniquet is used unless a temporary fixator prevents its placement.
- A large bump or a sterile triangle is used under the knee.
  - This allows for knee flexion, relaxing the gastrocsoleus complex and facilitating the reduction.
  - A sterile and removable one is most useful.
- The C-arm is brought in from the opposite side.
  - It should be angled so that it is parallel with the femoral shaft.
  - A notch view is useful for screw trajectories in the distal femur (FIG 10C, D).

### Approach

- The best-known approach for the treatment of distal femur fractures has been the straight lateral approach (FIG 11).
  - This is suitable for all fracture types, mostly types A and C1.
  - The incision may curve distally toward the tibial tubercle, and osteotomy may be performed.
  - Newer approaches include a lateral inverted U to allow better access to the joint and to allow for plate placement.
  - The minimally invasive lateral approach can be used for certain fractures and implants.
  - The joint must be visualized, reduced, and stabilized.
  - The placement of the plate on the shaft is done submuscularly, and reduction and fixation are done percutaneously under fluoroscopic guidance.
  - This is ideal for the LISS plate or plating system with targeting devices for the screws in the plate.
  - A modified anterior approach (the swashbuckler) has been described by Starr et al.7
    - This involves a midline incision.
    - A lateral parapatellar arthrotomy is done with elevation of the vastus lateralis as in the lateral approach.
A medial parapatellar arthroscopy can be used for retrograde intramedullary nailing or limited screw fixation.

- Mini-arthroscopy is used for the retrograde nail.
- Type B injuries may require a formal arthroscopy.
- A medial approach has been described.
- This is appropriate for type B2 and B3 fractures.

- It can be used in type C3 fractures if a second plate is being used (in conjunction with a lateral approach).
- A total knee approach has been described by Schatzker.6
- This is extremely helpful for type C2 or C3 fractures.
- It is used for plates but can be used for retrograde intramedullary nailing once the articular surface is reconstructed.
- A midline approach is used.
- An extended medial parapatellar arthroscopy is done.
- This allows exposure of the condyles for articular reduction.

A midline incision with a lateral parapatellar arthroscopy is my preferred exposure for type C fractures.

- A midline approach is used.
- A lateral parapatellar arthroscopy is done.
- Proximal extension is made into the quadriceps tendon, enough to repair to itself.
- Medial dislocation of patella is done.
- This allows exposure of the condyles for articular reduction and easier lateral plate insertion.
Chapter 11  ORIF OF THE DISTAL FEMUR  591

TEMPORARY BRIDGING EXTERNAL FIXATION

- A large external fixation system is used.
- A small bump is placed under the knee to place the knee in slight flexion.
- The injured extremity is brought out to length with manual traction.
- Two or three 5-mm Schanz pins are placed in the tibia in an anterior-to-posterior direction just medial to the crest to ensure intramedullary placement.
- Two or three 5-mm Schanz pins are placed in the femoral shaft in an anterior-to-posterior direction.
  - These should be placed out of the zone of soft tissue injury if possible.
  - The pins are placed while the limb is out to length so that the quadriceps is not “skewered” in a shortened position.
  - The pins can be placed outside of the anticipated plate location. This, however, has not been empirically found to be a problem. In my experience plates have often overlapped with pin sites and there has not been an associated problem with infections.
- Pin placement in the tibia may be altered if additional uses of such pins are needed, such as traction for an associated acetabular fracture (TECH FIG 1A).
- The bars can be configured in many ways, all of which provide temporary stabilization across the knee joint. I prefer a diamond configuration (TECH FIG 1B).

Reduction of the Metaphyseal Component

- Gross reduction of the metaphyseal component of the fracture should be performed with traction and manipulation of the pins.
- The fracture should be brought out to length.
  - Intraoperatively, the opposite leg can be used to help determine length.
  - Postoperatively, a scanogram can be used to determine whether the length has been regained before definitive fixation if there is extensive comminution, but this is not always needed (TECH FIG 2). Although the knee may be somewhat flexed, the scanogram can still be obtained and the femoral length determined as opposed to the entire leg length.
- The rotation should be checked once again before locking the external fixator construct, as described above under positioning. The same technique should be performed under sterile conditions.
- Varus–valgus alignment should be assessed before final tightening as well.
  - This can be done by using the Bovie cord intraoperatively and assessing the mechanical axis of the limb by fluoroscopically evaluating from the hip to the ankle with the cord centered at the femoral head all the way to the ankle.
  - The point at which the cord crosses the knee allows one to judge the varus–valgus alignment.

**TECH FIG 1**  
A. Bridging knee external fixation in patient with associated acetabular fracture; the tibial pin was used for traction purposes as well.  
B. A diamond configuration for bridging knee external fixation.
This technique can be used regardless of the locking plate system used. Each system’s technique guide should be reviewed before use, as each system has its own idiosyncrasies. Variations in plate application as well as reduction tools and techniques are unique to each system.

The temporary external fixator is prepared using a “double-double” technique.

The fixator is first prepared with a Betadine “scrub” (7.5% povidone–iodine) solution followed by a Betadine “paint” (10% povidone–iodine) solution (Beta–Beta preparation), followed by the extremity, with a second Beta–Beta preparation.

The surgeon then does an alcohol preparation, followed by iodine for the fixator, followed by alcohol and iodine on the skin.

This has been successful in our practice and allows for maintenance of traction during the preparation and aids in the actual surgery, functioning as a femoral distractor. (Chlorhexidine is used in iodine-allergic patients.)

An alternative is to completely remove the fixator components, except the pins, and wash, sterilize, and then reassemble the fixator on the patient after the leg has been prepared.

If there is no temporary bridging external fixator, the metaphyseal component of the fracture can be reduced and brought out to length with a femoral distractor, a temporary simple external fixator, or manual traction if adequate help is available.

Rotation of the proximal segment can be manipulated with the device used.

Midline Approach with an Extended Lateral Parapatellar Arthrotomy

A straight incision is made directly anterior about 5 cm proximal to the superior pole of the patella and distally to the level of the tibia tubercle (TECH FIG 3A).

The lateral skin flap is developed to allow for a lateral parapatellar arthrotomy (TECH FIG 3B).

The arthrotomy is performed, ensuring a cuff of tissue on the lateral aspect of the patella for repair as well as medially on the quadriceps (TECH FIG 3C).

The patella can be subluxed medially or inverted with knee flexion to allow exposure of the condyles (TECH FIG 3D).

Additionally, a blunt Hohmann retractor can be placed on the medial side at the level of the condyle to retract the patella.

The capsule is subperiosteally elevated off the lateral femoral condyle to allow for placement of the plate.

The lateral collateral ligament is preserved because the dissection is limited to the anterior two thirds of the lateral femoral condyle and plate placement is usually proximal to the lateral epicondyle.
The medial side in the metaphyseal region is left undisturbed as much as possible.

**Reduction of the Articular Surface**
- The joint is evaluated to determine comminution.
- Joint reconstruction is then performed with direct reduction. Each condyle is fully assessed first for smaller fracture fragments, with the goal of restoring each condyle anatomically. Small-diameter screws (less than 3.0 mm) may be used and can be countersunk underneath the articular surface.
- Large coronal fracture fragments are best treated with countersunk 3.5- to 4.5-mm lag-type screws. We use headless screws.
- Once each condyle is thought to be restored, or if a simple fracture pattern is present, the condyles should be reduced to each other using a large pointed reduction forceps (**TECH FIG 4A–C**).
- Each fragment can be rotated relative to another; this must be addressed as discussed before.
- The best way to assess this is under direct visualization and evaluating the reduction at the trochlear region of the patellofemoral joint.

Additionally, preoperative evaluation assessing the lateral radiograph can guide the surgeon. Intraoperative fluoroscopy to reassess the lateral view is also useful.
- Temporary Kirschner wires or the guide pins for the locking screws for the plate can be used for additional stabilization of the two condyles (**TECH FIG 4D**).

**Definitive Fixation of the Condyles**
- This can be accomplished outside the plate first and supplemented with screws through the plate. The area around the proposed plate, the “periphery,” can be used for the screw placement to avoid interference with the plate placement itself.
- If this is done, then the metaphyseal fracture does not necessarily have to be properly reduced before initial screw placement.
- Screws can also be placed from medial to lateral to avoid interference with the plate.
- Definitive fixation can be accomplished through the plate also (see next).
- If this is done, the metaphyseal component should be reduced to ensure the proper flexion–extension alignment of the shaft with the condyles.
This will ensure that the plate is collinear with the shaft once fixed to the distal segment. Otherwise, a malreduction in the sagittal plane will occur. The temporary Kirschner wires can be left in place to stabilize the joint.

**Reduction of the Shaft to the Distal Segment**

- Once the articular surface is temporarily stabilized or reduced, the reduction of the shaft to the distal segment should be performed before plate application.
- This can be temporarily stabilized with Kirschner wires or Steinmann pins.
- Alternatively, precisely placed bumps underneath the distal segment can be used to correct the extension of the distal segment and align it with the shaft.
- Adjustment or loosening of the temporary external fixator can aid in reduction if needed.
- The plate can then be placed submuscularly.

**Placement of the Plate**

- Each fixed-angle plating system is designed to help re-establish the valgus alignment of the distal femur.
- The screws in the distal portion of the plate are designed to be parallel to the joint surface.
- Thus, the initial guidewires for these screws should be placed parallel and confirmed by fluoroscopy.
- A distal “joint wire” can be placed to better evaluate this (TECH FIG 5A).
- Placing the distal screws parallel to the joint will help ensure that when the shaft is brought to the plate, the anatomic axis of the femur is restored.
- A distal screw trajectory guide is provided for some systems (TECH FIG 5B). This can be used to help ensure accurate placement of the plate distally, and initial guidewires can be placed through this.
- Once the wires are placed, the guide can be removed and replaced with the plate, using the wires as a guide.
- However, the shaft portion of the plate requires submuscular insertion, and thus the plate cannot be brought to an appropriate position to allow this to occur.
- To solve this, the guidewires can be driven through the medial side of the knee, which is distal enough to be safe (TECH FIG 5C).
- The plate can then be inserted submuscularly and the guidewires driven back through the plate laterally, thus aligning the plate to the distal segment and ensuring proper screw trajectory and plate placement (TECH FIG 5D,E).
- A single guidewire in a central hole will still allow flexion–extension placement of the plate if this needs to be adjusted.

After placing the initial guidewire parallel to the joint distally, and ensuring the fracture is reduced, the surgeon should obtain fluoroscopic visualization of the plate proximally on the shaft to ensure that the plate is on the bone (TECH FIG 5F,G).

To ensure placement of the plate on the bone both proximally and distally, it is best to stabilize the plate distally (where exposure is) using a guidewire in the center hole. This allows for a pivot point around which the anteroposterior positioning of the plate can be manipulated for the shaft. Fluoroscopy to image the lateral is then used to ensure placement.

Once the anteroposterior position is obtained, the plate is stabilized proximally.
The plate should be temporarily stabilized to the bone proximally.

Before the temporary stabilization, the length and rotation must be checked. Ideally, if the temporary fixator is in place, these two parameters have been maintained during the course of the operation.

If no screw targeting guide is present, a percutaneous provisional fixation pin can be used to stabilize the plate.

If a targeting guide is used, then a soft tissue guide for the most proximal hole is placed percutaneously and a drill bit or guidewire is used to stabilize the plate.

Again, the flexion–extension reduction should be checked.

This procedure creates our "box" construct, which aids in the placement of screws through the targeting device (if used) and in temporary stabilization of the fracture construct.
**Screw Placement**

- If the intercondylar split is going to be stabilized by screws through the plate, partially threaded screws or overdrilled fully threaded screws should be used first to provide interfragmentary compression.
  - Specially designed conical screws for certain systems exist, or large partially threaded screws can be used (larger than 4.5 mm). This also compresses the plate to the bone.
- Once the articular injury is addressed, at least two additional locking screws should be placed into the distal segment to secure the plate and the alignment.
- The trajectory of distal locking screws can be assessed on the notch view to ensure that penetration through the intercondylar notch does not occur (TECH FIG 6; see Fig 10C for C-arm setup and position for this image).
- Before placing the locking screws, the length, rotation, and alignment must be checked again if no fixator or distractor is in place holding the fracture alignment.
- The plate can be locked to the distal segment and then used to manipulate the distal segment relative to the shaft for the flexion–extension reduction.
- This, however, is predicated on proper distal alignment of the plate. Otherwise, once the plate is fixed to the distal segment in a malposition and the fracture reduced, the plate may be anterior or posterior on the shaft.

**TECH FIG 6** • Patient seen in Figure 10C,D, with the guidewire now pulled back and an appropriately sized screw placed.

**Attaching the Distal Segment to the Shaft**

- The distal segment is now fixed and can be attached to the shaft.
- If there is malalignment in the coronal plane but the sagittal plane alignment is reduced, the shaft can be “pulled” to the plate by means of various threaded devices or a nonlocking screw that can be placed freehand under fluoroscopic guidance or through a targeting jig (TECH FIG 7).

**TECH FIG 7** • The “whirlybird” device is tightened and the bone pulled to the plate.
Placement of Additional Screws

- Once proper reduction of the fracture is temporarily achieved and the plate in proper position, additional screws can be placed.
- If the targeting screw guide is used, percutaneous locking screws can be placed through the soft tissue drill or screw guides (TECH FIG 8A–C).
- If no targeting guide is available, fluoroscopic guidance and a percutaneous method can be used freehand.
- Depending on the system, locking drill guides can be placed freehand to ensure proper trajectory of the drill so that locking screws can be used.
- If that is not the case, nonlocking screws should be placed.
  - Experience is required for the freehand percutaneous method; otherwise, an open approach to the shaft should be performed.
- The final construct should be checked with fluoroscopy on the lateral aspect as well (TECH FIG 8D,E).

- The restoration of the mechanical axis can be checked intraoperatively after temporary stabilization (preferred) or definitive stabilization using the Bovie cord.
- TECHNIQUES FIGURE 8F–H show the repair after definitive stabilization.
- The exact number of screws in each fragment has yet to be determined in the literature, but we prefer to have at least five screws in each fragment if possible at the end of fixation.
- A longer working length in the shaft can be used, and not all holes need to be filled.
- There is evidence that in young patients with good bone, no locking screws are needed in the diaphysis.
- Multiple locking screws are used in the epiphysis because of the short length of these distal fragments.
- The largest screws available for the epiphysis should be used.

TECH FIG 8 • A. Targeting guide for proximal screws. B. C-arm image of screws placed. C. Stab incisions used for percutaneous method. D,E. Plate placement on the lateral aspect is confirmed. (continued)
TECH FIG 8 • (continued) F–H. Alignment is checked intraoperatively with the Bovie cord. The mechanical axis from the center of the femoral head through the middle of the knee to the middle of the ankle is confirmed.

Bone Grafting
- The metaphyseal comminution may require bone grafting in cases of open fractures with bone loss.
- The exact type and need vary and should be based on the surgeon’s experience (TECH FIG 9).
- Hemostasis is achieved throughout the procedure or after the tourniquet is released. A tourniquet can be used to help minimize bleeding and improve visualization, especially for articular reconstruction. Often a sterile tourniquet is used because of the temporary bridging external fixator that is in place.
- After adequate irrigation (before bone graft or substitute placement if used), a drain is placed in the knee joint and brought out laterally.

TECH FIG 9 • A. Patient with significant metaphyseal bone loss from an open injury shown on CT scan. B. The post-fixation radiograph shows the void. C. Placement of Osteoset beads impregnated with vancomycin (off-label use) to fill the void and provide osteoconductive material for healing.
Chapter 11 ORIF OF THE DISTAL FEMUR

TECHNIQUES

Standard Wound Closure

- Closure of the arthrotomy is performed with figure 8 0 Vicryl sutures. This is reinforced by a running 2-0 Fiberwire suture (TECH FIG 10A).
- The subcutaneous tissue is closed with 2-0 Vicryl.
- The skin is closed with staples, as are the percutaneous stab incisions.
- The knee is flexed and extended fully to ensure restoration of motion as well as to break any adhesions in the quadriceps that may have formed while the temporary bridging external fixator had been in place (TECH FIG 10B,C).
- The final radiographs are taken in the operating room (TECH FIG 10D,E).

TECH FIG 10 • A. Closure of the arthrotomy. B,C. Full flexion and extension of the knee after definitive fixation and closure. As seen in final AP (D) and lateral (E) radiographs, the metaphyseal comminution is bridged and left undisturbed.

Limited Lateral Approach

- A lateral incision measuring about 5 to 6 cm is made starting at the level of the joint and extending proximally in line with the shaft. The distal extent is curved slightly toward the tibial tubercle, as in the lateral approach (TECH FIG 11A,B).
- The iliotibial band is incised in line with the skin incision (TECH FIG 11C).
- The dissection is carried down to the lateral femoral condyle. The lateral aspect is exposed enough for plate placement (TECH FIG 11D).
- A Cobb elevator is used to create a plane submuscularly up the lateral shaft of the femur for placement of the plate.

OPEN REDUCTION AND INTERNAL FIXATION OF THE DISTAL FEMUR WITH LOCKING PLATES (TYPE A OR NONDISPLACED TYPE C1 OR C2)

- This technique can be used regardless of the locking plate system used. Each system’s technique guide should be reviewed before use, as each system has its own idiosyncrasies. Variations in plate application as well as reduction tools and techniques are unique to each system.
- See comments above regarding temporary use of an external fixator or distractor.
TECH FIG 11 • Patient with closed distal femur fracture (also shown in Figs. 4G,H and 5C–E). A. Limited lateral incision, with the tibial tubercle marked. B. Skin incision showing the iliotibial band. C. Incision of the iliotibial band. D. Exposure of the lateral aspect of the femur.

Stabilizing the Articular Surface

- For nondisplaced type C1 or C2 fractures, the first priority is to stabilize the articular surface.
- Visualization of the joint may be accomplished with placement of a blunt Hohmann retractor (or similar Z retractor) (TECH FIG 12A).
- A reduction forceps is placed anteriorly to hold the reduction (TECH FIG 12B).
- Temporary Kirschner wires or guidewires from a cannulated system can be placed for additional stability (TECH FIG 12C,D).
- All clamps, Kirschner wires, or guidewires should be placed outside the zone of plate application (TECH FIG 12E,F).
- Definitive fixation of the condyles should be performed (see technique description above) (TECH FIG 12G).

TECH FIG 12 • A. Visualization of the joint for articular reduction. B. C-arm image of reduction forceps holding the intercondylar split reduced. C,D. Clinical photographs with forceps followed by guidewires for screw placement. E,F. Lateral views showing pins and wires outside the zone for either plate application or intramedullary nail. The anterior and posterior placement of the pins is seen. (continued)
Chapter 11  ORIF OF THE DISTAL FEMUR

Reduction of the Distal Segment and Plate Placement
- Reduction of the distal segment to the shaft can be performed using temporary Steinmann pins (TECH FIG 13).
- The plate can now be applied in a submuscular fashion (see Placement of the Plate, above).

Wound Closure
- Final radiographs are taken in the operating room (TECH FIG 14).
- Standard wound closure is undertaken, as described in the previous section.

Retrograde Nailing
- Refer to Chapter TR-9 on retrograde nailing of the femur.

PEARLS AND PITFALLS

| Articular reduction | • Direct open reduction should be used.  
|                     | • It can be outside the plate or through the plate.  
|                     | • Screws should be out of the way of the plate or nail. |
| Plate application   | • The initial guidewire through the central hole in the plate should be parallel to the joint. Ninety-five degrees is built into the plate. If locking screws are placed parallel to the joint, then once the plate is reduced to the shaft, the proper alignment is restored.  
|                     | • Rotation must be continually assessed.  
|                     | • The fracture should be reduced in the sagittal plane before temporary fixation or creation of a “box construct” with the plate.  
|                     | • In comminuted cases, a scanogram or opposite-side femur film with a ruler can be obtained to help determine the length. |
| Soft tissue handling | • The surgeon should avoid stripping the soft tissues medially. This will obviate the need for bone grafting.  
|                     | • The plate should be placed submuscularly. |
**POSTOPERATIVE CARE**

- The goal of stable fixation is to allow early range of motion. My preference is a hinged knee brace locked in extension for 2 weeks, at which time the wound is healed and full motion is then started.
- A continuous passive motion machine can be used.
- Cold therapy products can be used.
- A drain is used for 48 hours postoperatively.
- Deep vein thrombosis prophylaxis may be indicated for certain patients:
  - Obese
  - Multiply injured
  - History of previous deep vein thrombosis
  - Patient who may not be mobile enough despite an isolated injury
- We provide 2 weeks of deep vein thrombosis prophylaxis for all patients and then reassess in terms of mobility if it is an isolated injury. Otherwise, with significant risk factors or indications for deep vein thrombosis prophylaxis, a full 6-week course is prescribed.
- Early protected weight bearing
  - Toe-touch weight bearing for 6 to 8 weeks for plate fixation
  - Followed by partial weight bearing for 4 to 6 weeks for plate fixation
  - Followed by full weight bearing
  - Immediate weight bearing can be indicated for fixation of type A fractures with intramedullary nailing if the fracture pattern is stable and not comminuted.
  - For type C fractures treated with intramedullary nailing and screw fixation for the articular component, toe-touch weight bearing or non-weight bearing for 6 to 8 weeks is adequate, followed by full weight bearing.
  - In all cases, progression of weight bearing is based on radiographic evidence of healing.
- Patients are prescribed physical therapy for range of motion and strengthening at 2 weeks.

**OUTCOMES**

- Results are good to excellent in 50% to 96% of cases.\(^3,5,9\)
- Average range of motion is about 110 to 120 degrees.
- About 70% to 80% of patients can walk without aids.
- It is difficult to compare the results of studies in the literature.\(^9\)
  - There is no universally accepted classification.
  - There are varying indications.
  - Different grading systems are used.
  - Not all authors adhere to the same principles.

**COMPLICATIONS**

- Neurovascular injuries
  - Can occur from initial trauma
  - Rare after surgery
- Infection
  - 0% to 10% rate after open reduction and internal fixation
  - Predisposing factors:
    - High-energy injuries
    - Open fractures
    - Extensive dissection
    - Prolonged operative time
    - Inadequate fixation
- Nonunion
  - 0% to 6% rate after open reduction and internal fixation
  - Predisposing factors:
    - Bone loss or defect (FIG 12A)
    - High-energy injuries
    - Soft tissue stripping
    - Loss of osseous vascularity
**Inadequate stabilization**
- No bone graft
- Infection

**Malunion**
- More common with nonsurgical treatment, which results in varus and recurvatum
- Operative treatment with newer locking plates can result in valgus.
- Treatment required to restore mechanical axis:
  - Supracondylar osteotomy
  - Stable fixation
  - Early range of motion

**Hardware failure occurs in 0% to 13% of cases** *(FIG 12B,C).*
- Predisposing factors:
  - Communion of metaphyseal area
  - Older age
  - Very distal fracture
  - Premature loading or weight bearing
  - Nonunion
  - Infection
- Knee stiffness: almost all patients exhibit some loss of motion
- Protruding hardware
- Articular malreduction
- Adhesions
  - Intra-articular
  - Ligamentous-capsular contractures
  - Muscle scarring
- Treatment may consist of any of the following or combination of:
  - Manipulation
  - Arthroscopic lysis
  - Formal quadricepsplasty

**Posttraumatic arthritis occurs in 0% to 30% of cases.**
- Predisposing factors:
  - Severe articular comminution
  - Cartilage loss
  - Cartilage impaction or damage
- Surgical factors:
  - Failure of anatomic reduction
  - Malalignment of fracture

**REFERENCES**
DEFINITION
- The patella, the largest sesamoid bone, is a key part of the knee extensor mechanism and provides leverage to the quadriceps mechanism. Fractures of the patella have the potential to disrupt the extensor mechanism.
- Fractures of the patella also affect the knee joint itself by interrupting the articular surface.
- Management of patellar fractures must restore any disruption of the extensor mechanism while ensuring minimal disruption of the articular surface.
- Stellate or comminuted, transverse, vertical, apical or inferior pole, and sleeve fractures are common descriptive terms used in the classification of patellar fractures.

ANATOMY
- The articular surface is composed of medial and lateral facets, with the medial facet having the most variability in size and shape. Horizontal ridges further subdivide the medial and lateral facets. An odd facet lies at the most medial aspect of the articular surface. The distal pole of the undersurface is extraarticular (FIG 1).
- The superior pole of the patella serves as an attachment for the quadriceps tendon. The most superficial portion of the quadriceps tendon courses over the anterior patellar surface and is contiguous with the patellar tendon. The patellar tendon courses from the apex of the patella to the tibial tubercle.
- The patellar retinaculum is composed of thickenings of the fascia lata of the thigh in addition to the aponeurosis of the vastus medialis and lateralis.13 In addition to stabilizing the patella, the retinaculum acts as a secondary extensor.
- Multiple arteries about the knee supply a peripatellar plexus, although the main intraosseous blood supply is from a distal-to-proximal direction.14
- The patella acts to increase the moment arm of the extensor mechanism by displacing the quadriceps tendon anteriorly. This increased moment arm is most critical during terminal extension, when the quadriceps is otherwise at a mechanical disadvantage.9
- Due to the small contact area of the articular surface and the high level of compressive forces generated by the extensor mechanism, the contact stress on the patellofemoral joint has been estimated to be higher than any other major weight-bearing joint.5

PATHOGENESIS
- Fractures of the patella may result from direct force to the anterior knee, indirect forces transmitted through the extensor mechanism, or a combination of both.
- The patella is particularly susceptible to injury from direct blows given its small amount of tissue covering and its prominence.
- The portion of the patella articulating with the femur moves from distal to proximal with increasing degrees of flexion. The fracture pattern for direct blows to the patella has been shown to correspond to the articulating portion of the patella at the time of injury, thus corresponding to the amount of knee flexion at time of injury.1
- Indirect forces causing fracture can be caused by unanticipated and rapid flexion of the knee while the quadriceps is also firing. Fractures from an indirect mechanism tend to be less comminuted than those from direct trauma.5

FIG 1 • Patellar anatomy. The major facets include the medial, lateral, and odd facets. The medial and lateral facets are further subdivided by subtle horizontal ridges.
NATURAL HISTORY

- Depending on the type of fracture and involvement of the retinaculum, various amounts of long-term extensor weakness can be expected. The long-term effect on range of motion is likewise dependent upon fracture pattern and displacement.
- There is an increased incidence of osteoarthritis of the knee after patellar fracture. The increased rate of arthritis may be both from initial cartilage injury and posttraumatic arthritis due to articular cartilage incongruity.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Physical examination findings are as follows:
  - Often a defect can be palpated in the patella.
  - New onset of joint effusion after injury localizes injury to within the capsule of the knee. A knee effusion may not be present if there is disruption of the retinaculum, allowing hematoma to escape from the joint capsule.
  - The placement of the patella and palpation of defects with the patella, quadriceps tendon, or patellar tendon can help differentiate between patellar fracture and ligamentous extensor disruption.
  - Pain can limit the ability to test for active extension of the knee or for extensor lag. Introduction of local anesthesia after aspiration of hematoma can aid in assessment of extensor function. The surgeon should note any extravasation of local anesthetic to evaluate intra-articular extension of skin defects.
  - Aspiration: The surgeon notes the amount of fluid aspirated. The presence of fat lobules in the syringe signifies a fracture extending into the knee capsule.
  - Patients with patellar fractures are able to actively extend the knee in marginal or longitudinal fracture types or with intact secondary extensors (ie, retinaculum). Knee extension is usually not possible with displaced transverse fractures.
  - History is critical in determining a direct versus indirect cause of fracture. Patella fractures caused by a high-energy direct cause (ie, head-on motor vehicle accident with dashboard injury) are often associated with other injuries to the knee.
  - Peripheral pulses and neurologic function must be examined.
  - Knee stability should be evaluated. Patella fractures may be accompanied by cruciate ligament injury.
  - Open fractures will require urgent operative management and are associated with an increased rate of nonunion and infection. Open fractures also connote higher energy and an increased likelihood of associated injury.
- Physical examination must include a thorough secondary survey for other associated injuries. Distal femur fractures and acetabular injuries are commonly associated in high-energy motor vehicle accidents owing to transfer of force through the flexed knee.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior (AP) and lateral views of the knee and an axial view of the patella provide sufficient information for nearly all fracture types.
- In the trauma setting, the Merchant view11 is the best tolerated (FIG 2A).
- A bipartite patella, arising from failed fusion of patellar ossification centers, can be mistaken for a fracture. Bipartite patellae are most commonly located superolaterally and occur more frequently in males. In 40% of individuals with a bipartite patella, the contralateral patella will also be bipartite7 (FIG 2B,C).
- The normal Insall-Salvati ratio (height of the patella over the distal from the inferior pole to the tibial tubercle) is about 1.0. Values less than 1 represent patella alta and possible patellar tendon rupture. Patella alta may also be seen in patellar sleeve fractures in the pediatric population.

DIFFERENTIAL DIAGNOSIS

- Quadriceps rupture
- Patellar tendon rupture
- Bipartite patella
- Ligamentous or meniscal injury
- Distal femur or tibial plateau fracture
- Inflammatory arthritis or septic arthritis
- Osteochondral injury
- Patellar dislocation or retinacular injury

NONOPERATIVE MANAGEMENT

- Fractures must meet two criteria to be managed nonoperatively:
  - No associated extensor mechanism disruption
  - Less than 2 mm of displacement of the articular surface or less than 3 mm separation of the fracture fragments.3,6 (Less
displacement is tolerated by some authors in the presence of transverse fractures.\(^4\)

- The described period of immobilization varies. Historically, patients were kept in a long-leg cast for 4 to 6 weeks. Current nonoperative management involves early functional treatment.
- Our preference for nonoperative treatment includes partial weight bearing with crutches and a hinged knee brace.
  - The leg is maintained in extension for 2 weeks, 0 to 45 degrees of flexion for 2 weeks, and 0 to 90 degrees for 2 weeks, followed by full motion for 2 weeks.
  - After this 8-week course, full weight bearing is allowed.
- Nonoperative management of appropriate fractures results in good overall results, with loss of flexion the most common complication.\(^4,5\)

**SURGICAL MANAGEMENT**

- Operative treatment is the preferred treatment for the majority of fractures not meeting the nonoperative criteria outlined above. Treatment is aimed at anatomic reconstruction of the articular surface and restoration of the extensor mechanism.
- Open reduction and internal fixation is the treatment of choice.
- Cases with severe comminution of the inferior or superior pole may be considered for partial patellectomy.
- Total patellectomy is reserved for cases of severe comminution involving most of the patella in which reconstruction of an articular surface is not possible.
- Methods involving arthroscopy or external fixation have not gained widespread use.
- Soft tissue must be respected as there exists only a thin soft tissue envelope covering the patella. This care for soft tissue begins in the emergency department. Splints or knee immobilizers must be accompanied by copious padding to minimize complications from pressure.

**Preoperative Planning**

- Operative timing is dictated by patient condition, presence of open fractures, and condition of the soft tissues.
- Fracture imaging is reviewed.
- Examination under anesthesia is critical, as evaluation of coexisting ligamentous injuries is often limited by patient pain prior to surgery. Lachman, pivot shift, posterior drawer, and varus-valgus testing should be undertaken before preparing the surgical site.
- Concomitant injuries may be addressed in the same surgery.

**Positioning**

- Patients are placed in the supine position on a radiolucent table.
- If a tourniquet is used, it must be placed as proximally as possible on the thigh. The quadriceps must not be trapped under the tourniquet, as this may retract the patella superiorly, hindering fracture reduction. The knee is flexed to 90 degrees before elevating the tourniquet. If the retinaculum is disrupted and the superior patella is high-riding, the quadriceps should be pulled distally before inflating the tourniquet.\(^18\)

**Approach**

- Longitudinal or transverse incisions may be made.
- We use a longitudinal approach to facilitate exposure and allow extension to the tibial tubercle for wire augmentation when needed. A longitudinal approach may be better tolerated for future reconstructive surgeries and may therefore be beneficial in elderly patients or patients with preexisting osteoarthritis.
- A transverse approach follows the skin lines and may be preferable cosmetically. A transverse approach minimizes risk of injury to the infrapatellar branch of the saphenous nerve.
- Dissection is carried through the patellar bursa to expose the fracture site. Hematoma is often encountered upon opening bursa. Hematoma is cleared from the fracture site with copious irrigation and small curettes. The fracture line is followed to the retinacular tissue; the surgeon identifies the superior and inferior leaves of retinaculum and tags them for later repair.

---

**FIG 2 • (continued) B,C. Bipartite patella. Note the classic superolateral position of this multipartite patella and the sclerotic margins.**

---
TENSION BAND WIRING

- Tension band wiring can be used to stabilize transverse fracture patterns. More complex fracture patterns can use a tension band construct if the fracture can be converted to a transverse pattern by fixation of smaller comminuted pieces with screws or Kirschner wires. Tension band constructs may also be used for more distal pole fractures, with Kirschner wires placed more closely together to capture the fragment.

- Two 1.6- to 2.0-mm Kirschner wires will span the fracture in parallel (TECH FIG 1A). They can be introduced through the fracture site into the proximal fragment in a retrograde fashion or into the distal fragment in an antegrade fashion.

  - The Kirschner wire is delivered until flush with the fracture line, and the fracture reduction is obtained and held with patellar reduction clamps or Weber clamps.

  - Fracture reduction is checked by palpating the articular surface with a Freer elevator (or by finger palpation if the rent in the retinaculum allows). When encountered, small articular fragments without attached subchondral bone may be discarded. Depressed articular fragments are gently reduced by a Freer elevator.

  - Once the fracture is sufficiently reduced, the Kirschner wire is delivered through the opposite fracture fragment.

  - A lateral fluoroscopic view may help to ensure appropriate fracture reduction and Kirschner wire placement.

- Ideally, the Kirschner wires will be about 5 mm below the anterior surface of the patella. The Kirschner wire should be clipped to leave roughly 1 cm of prominence below the inferior pole of the patella.

- A 1.0-mm-thick cerclage wire is passed just deep to the Kirschner wires, abutting the superior pole of the patella. Care must be taken to leave little to no intervening soft tissue between the superior patella and the tension band.

- A 16-gauge angiocath may be passed through the quadriceps mechanism and the wire advanced through the catheter to aid in placement of the wire (TECH FIG 1B).

  - The cerclage wire is passed distally in a similar fashion, ensuring the wire abuts the distal pole of the patella.

  - The wire is looped around the anterior aspect of the patella.

  - Alternatively, the wire may be crisscrossed in a figure 8 pattern.

  - Prior to tensioning, the surgeon verifies that the Kirschner wires capture the cerclage wire.

  - To ensure even tensioning, a two-loop tensioning technique is used. A twist is made in the cerclage wire on the opposite side of the two free ends of the wire. The free ends are gently twisted. These two loops are sequentially tightened with a large needle driver (TECH FIG 1C). The loop is lifted to tension the wire and then twisted.

---

TECH FIG 1 • Tension band fixation. A. Fracture reduction is maintained with a Weber clamp while Kirschner wires are passed. B. A large angiocath is used for ease of wire placement deep to Kirschner wires and beneath the quadriceps tendon. (continued)
As advocated by Carpenter et al, cannulated screws may be used in place of Kirschner wires in a tension band construct for transverse fracture patterns (TECH FIG 2A–C). This construct has shown to be superior biomechanically to the Kirschner wire tension band construct, resisting larger forces and resulting in less fracture gaping with loads.\(^5\)

Wires are sequentially tensioned until appropriate compression is visualized and palpated at the fracture site.
- The ends of the twists are clipped, bent over, and tamped into bone to minimize prominence.
- The superior portion of the Kirschner wire is bent and then cut, leaving a hook to capture the cerclage wire. The Kirschner wire is rotated and tamped into the superior pole of the patella. The inferior tip of the wire is cut to avoid excessive length within the patella tendon while leaving enough wire to maintain position of the cerclage wire (TECH FIG 1D).

Retinacular defects are repaired with absorbable braided suture, a critical step in restoring the extensor mechanism.
- The tourniquet is deflated and hemostasis obtained. A suction drain is placed as needed and the wound is closed with buried absorbable sutures followed by simple nylon sutures.
- A well-padded sterile dressing is applied with padding over the leg from the malleoli to the proximal thigh. A knee immobilizer is placed.

MODIFIED TENSION BAND WITH CANNULATED SCREWS

Reduction is obtained as described above, with the guide-wires for the 4.0- or 4.5-mm partially threaded cannulated screws used in place of Kirschner wires.
- Screws are placed over the guidewires using a lag technique and are left short of the distal cortex. A lateral fluoroscopic view is helpful in verifying screw placement.
INTERFRAGMENTARY SCREWS WITHOUT TENSION BANDING

- Although occasionally used with tension band constructs to convert complex fracture patterns into transverse patterns, screw fixation can also be used alone (TECH FIG 3). This construct is particularly suited for simple fracture patterns with articular displacement and an intact retinaculum.

- Lag screw fixation is often the method of choice for longitudinal fractures requiring operative management. Lag screw fixation for transverse fractures is also a suitable option, especially in patients with good bone stock. Multiple biomechanical studies have shown two cortical lag screws to be nearly as strong as or stronger than tension band alone.

- After obtaining reduction with pointed forceps, 3.5-mm or 4.5-mm cortical screws are used in lagging fashion across fracture sites.

- Closure and retinacular repair are undertaken as described above.
PARTIAL PATELLECTOMY

- Partial patellectomy is often advocated for comminuted fractures of the patella when a portion of the patella is significantly comminuted. Often this comminution occurs at the patellar pole, with inferior pole fractures being more common.
- After a standard approach as above, the comminuted fracture fragments are identified. If restoration of the comminuted site is not possible, the comminuted fragments are removed. Preservation of as large a portion of the articular surface as possible is critical.
- Multiple longitudinal drill holes are made through the remaining portion of the patella such that the entrance point of the tendinous attachment will be as near to the articular surface as possible. The amount of holes is equal to the number of sutures plus one.
- Nonabsorbable suture with a tendon grasping stitch is used to attach the adjacent tendon (usually patellar tendon) through the drill holes. Suture is tied with the knee in neutral or hyperextension (TECH FIG 4).
- Repair may be augmented by a tension band construct through the patella and tibial tubercle or by Mersilene tape, although we do not commonly perform such augmentation.
- Retinaculum is repaired with absorbable suture.
- Closure is as described above.

TECH FIG 4 • Partial patellectomy. A. Comminuted distal pole of patella fracture, an ideal fracture pattern for the construct. B. Suture placement prior to tensioning and tying. Two sutures and three drill holes are used.
PEARLS AND PITFALLS

The surgeon should ensure that tension band wires have little to no intervening tissue between the wire and the patella when passing under the Kirschner wires at the proximal and distal poles. ▪ This common error can cause fracture site distraction. When the fracture is loaded, the fragments can displace on the Kirschner wire until the tension band becomes taut.5

Cannulated screws must be left short of the far cortex if used with a tension band construct. In contrast, when using screw in a lagging fashion, bicortical purchase affords a better construct. ▪ Protrusion of the screw past the distal cortex creates a stress riser in the tension band.5 Additionally, the tension band does contact the screw tip rather than the bone, lessening compression forces on the bone through the tension construct.

There is a delicate balance between early range of motion to promote better long-term range of motion and protection of fixation to avoid loss of reduction. ▪ Passive range-of-motion exercises ought to begin as soon as surgeon comfort allows. Intraoperative knee range of motion resulting in gaping at the fracture site and poor intraoperative bone stock may lead to the decision for delayed passive range of motion.

When possible, complex fracture patterns are converted into simpler or transverse patterns. ▪ Fixation of longitudinal comminuted fragments with interfragmentary screws often allows the fracture pattern to be treated as a simpler transverse pattern.

POSTOPERATIVE CARE

▪ Passive knee range of motion and gentle active range of motion begins once soft tissue healing is ensured. We use an abundance of padding postoperatively underneath any bracing until postoperative soft tissue swelling resolves.

▪ Patients are allowed to bear partial weight with crutches and the knee fully extended in a knee immobilizer or hinged knee brace immediately postoperatively.

▪ We prefer 2 weeks with the knee in extension, 2 weeks of knee flexion from 0 to 60 degrees, and 2 weeks of full knee flexion in a hinged knee brace.

▪ Full weight bearing out of a brace is allowed once signs of fracture healing are evident on postoperative imaging, and not before 6 weeks.

▪ Although straight leg raising and quadriceps sets with the knee extended may begin immediately postoperatively, quadriceps strengthening with resistance is held until signs of fracture healing appear.

▪ For fracture fixation deemed unstable during intraoperative range of motion, initiation of knee motion may be held until fracture healing is evident.

▪ Rehabilitation must keep in mind the compressive forces on the patella during knee flexion. Compressive forces are greater than three times body weight during stair climbing and reach nearly eight times body weight while squatting.10

OUTCOMES

▪ Outcomes depend on maintenance of fracture reduction.

▪ In a review of 320 patients with patellar fractures (212 treated nonoperatively) with a mean follow-up of 8.9 years, Bostrum3 reported that 24% of patients did not consider themselves fully recovered; moderate or severe pain persisted in 31% of patients. The range of mobility was normal in 90% of patients, with the majority of restriction of motion in elderly patients. Ninety-one percent of patients had fracture union.

▪ Functional outcomes after long-term follow-up of tension band wiring have been reported to be the same as age-matched standards.13

COMPLICATIONS

▪ The historical complication rate of operative intervention for patellar fractures varies in the literature. Although a recent study on perioperative complications reported a rate of 25%,16 historical rates are much lower.4

▪ Infection rates are low and can be minimized by the use of perioperative antibiotics and careful soft tissue handling. Few postoperative infections are deep infections involving the joint.3,16

▪ Patients often note palpable hardware, given the thin overlying tissue. Although we do not routinely remove hardware, patients in whom the hardware becomes symptomatic may have hardware removal after fracture consolidation. Hardware removal rates have varied in the literature from 10% to 60% with tension band constructs.15,16

▪ Smith et al16 reported fracture displacement of more than 2 mm in 22% of patients treated with tension band wiring. All patients with significant displacement requiring reoperation were weight bearing without bracing between 3 and 5 weeks. In the remainder of cases with loss of fixation, the most common cause was technical error.

▪ Nonunion with tension band techniques is a rare complication, occurring in less than 1% of fractures fixed in this manner.5

▪ Decreased knee range of motion is another possible complication. Flexion is more commonly lost than extension. At times this loss of motion can be due to intra-articular adhesions and can benefit from arthroscopic release.

▪ As with many intra-articular fractures, osteoarthritis develops in the injured extremity at a rate greater than that of the uninjured extremity. Reported rates of osteoarthritis vary greatly.

REFERENCES

DEFINITION
- Bicondylar tibial plateau fractures involve both medial and lateral plateaus.
- Schatzker type 5 fractures (FIG 1A,B) involve both condyles without complete dissociation from the shaft. Thus, a portion of the joint is still attached to the shaft. They are usually amenable to medial and lateral buttress plate fixation.
- Schatzker type 6 fractures (FIG 1C,D) involve both condyles with complete dissociation of the articular segment from the shaft.
- Lateral fractures with associated posterior medial fragments should be distinguished from other bicondylar types, as they often require posteromedial fixation independent from lateral fixation and may be representative of fracture-dislocation (see Fig 3).

ANATOMY
- In the loaded knee, the medial plateau bears about 60% to 75% of the load.7,8
- The medial plateau is larger than the lateral plateau (FIG 2).
  - The medial plateau is concave, the lateral plateau convex.
  - Stronger, denser subchondral bone is found on the medial side due to increased load.
- The lateral plateau is higher than the medial plateau. The medial proximal tibial angle is 87 degrees relative to the anatomic axis of the tibia (range 85 to 90 degrees).6
  - The proximal posterior tibial angle is 81 degrees relative to anatomic axis of the tibia (range 77 to 84 degrees).6
  - The iliotibial band inserts on the tubercle of Gerdy.
  - The anterior cruciate ligament attaches adjacent and medial to the tibial eminence. It acts to resist anterior translation of the tibia relative to the femur. Recognizing a fracture fragment that contains this attachment can be important to re-establish stability to the knee.
  - The posterior cruciate ligament attaches about 1 cm below the joint line on the posterior ridge of the tibial plateau and a few millimeters lateral to the tibial tubercle.
    - The function of the posterior cruciate is to resist posterior tibial translation of the tibia relative to the femur. This acts as the central pivot of the knee.
  - The medial collateral ligament resists valgus force.
    - The medial collateral ligament originates on the medial femoral epicondyle and inserts on the medial tibial condyle.
  - The lateral collateral ligament resists varus force and external rotation of the femur.
    - The lateral collateral ligament originates on the lateral epicondyle of the femur and attaches to the fibular head.
  - The menisci, medial and lateral, are crescent-shaped fibrocartilaginous structures that act to dissipate the load on the tibial plateau, deepen the articular surfaces of the plateau, and help lubricate and provide nutrition to the knee.
    - The medial meniscus is more C-shaped and the lateral meniscus is more circular in shape.
- The lateral meniscus is more mobile than the medial meniscus.

PATHOGENESIS
- Bicondylar tibial plateau fractures are typically caused by a high-energy mechanism with associated injury to surrounding soft tissue.
- The mechanism responsible for injury is primarily an axial force, which may be associated with a varus or valgus moment.
  - With a valgus force, the lateral femoral condyle is driven wedge-like into the underlying lateral tibial plateau.5
  - The size of the fracture fragments depends on multiple factors, including localization of the impact, the magnitude of the axial force producing the fracture, the density of the bone, and the position of the knee joint at the moment of trauma.
  - Ligament injuries have been found to occur in 20% to 77% of tibial plateau fractures.3,4
  - Repair of ligament injuries at the time of fracture fixation is controversial. Some advocate ligament repair at the time of fracture fixation, while others feel that if the fracture can be reduced there is no need for early ligament repair.

NATURAL HISTORY
- Joint incongruity can predispose to arthrosis.
- Inadequate fracture stability can lead to varus-valgus collapse.
- Joint stiffness
- Joint instability can result from associated ligament injury.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Generally, a bicondylar injury pattern is caused by a high-energy mechanism. It may also be seen with a low-energy mechanism, such as a fall from standing height or in an older patient with osteoporosis.
  - The patient will complain of a painful swollen knee and will have difficulty bearing weight on the extremity. Hemarthrosis will be present if the capsule has not been disrupted.
  - The patient history should include details of the injury mechanism, preinjury ambulatory status, and any previous injury and disability.
  - A complete examination is required to rule out other injuries. The vascular status of the limb proximal and distal to the injury requires evaluation.
  - If there is an abnormality on palpation pulses, a vascular consult may be needed.
  - The ankle–brachial index of the extremity, along with ultrasound examination of the leg, can be helpful in fully evaluating the possibility of vascular injury, which occurs in about 2% of these fractures.1,9 The patient is evaluated for compartment instability, and the vascular status of the limb proximal and distal to the injury is assessed.
**FIG 1** • **A,B.** AP and lateral views of a Schatzker type 5 bicondylar tibial plateau fracture. **C,D.** AP and lateral views of a Schatzker type 6 bicondylar tibial plateau fracture.

**FIG 2** • **A, B.** AP (A) and axial (B) views of the tibia showing the relevant anatomy.
syndrome by palpating the lower extremity compartment for swelling and passively extending the muscles in the lower extremity, noting any increase in pain.

- The strength of dorsiflexion and eversion will help evaluate the peroneal nerve. It is important to examine and document peroneal nerve function before surgery because of the possibility of a stretch injury. Motor and sensory function of the nerve proximal and distal to the injury should be assessed.
- A thorough ligament examination of the knee is needed, although this can be difficult preoperatively owing to difficulty differentiating ligamentous from bony instability.
- Examination of the knee ligaments should therefore take place after operative stabilization and before the patient is awake in the operating room.
- Soft tissues need careful inspection before definitive surgical intervention can take place. The surgeon should note where surgical incisions will be located when evaluating the soft tissue.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Anteroposterior (AP) and lateral radiographs of the knee and tibia, and oblique views of the knee (FIG 3A–C).

  - CT scan with sagittal and coronal reconstruction is helpful to define complex fracture patterns and to plan surgical tactics (FIG 3D,E).
  - MRI is useful in evaluating ligament and meniscal injury around the knee.

**DIFFERENTIAL DIAGNOSIS**

- Unicondylar tibia fracture
- Patella fracture
- Ligament injury at the knee
- Proximal tibial shaft fracture
- Extensor mechanism disruption

**NONOPERATIVE MANAGEMENT**

- A fracture brace, a long-leg cast, or both may be used to treat low-energy nondisplaced fractures.
  - These require close observation to ensure progressive malalignment (particularly varus) does not occur.
- A long-leg cast, a fracture brace, or both can be used in treating low-energy, minimally displaced fracture patterns. It may also be used if patient factors (eg, comorbidities, functional status) would make operative intervention inappropriate.
SURGICAL MANAGEMENT

Preoperative Planning

- The surgeon should thoroughly review all preoperative imaging studies.
- A surgical approach is planned that affords adequate exposure for reduction and stabilization of the fracture.
  - Single lateral, dual incisions and occasionally a posterior approach are most common.
  - Single anterior incisions with stripping should be avoided if medial and lateral exposure is required.
- A tactic for fracture reduction is planned based on preoperative imaging.
  - Consideration should be given as to whether a femoral distractor will be useful.
  - In bicondylar fracture patterns, joint distraction is marginal with use of a femoral distractor, as distraction takes place through the fracture rather than across the joint.
- The surgeon should decide which part of the bicondylar pattern to stabilize first. By approaching the posteromedial side first and obtaining the reduction on the medial side before approaching the lateral tibial plateau, the surgeon may help prevent stabilizing the knee in varus. If the medial side can be reduced percutaneously and the fracture pattern is amenable to lateral locked plating only, the surgeon may be able to avoid dual incisions. These decisions can be made in preoperative planning.
- Patient positioning should be planned to ease surgical exposure. It is usually supine, except when a posterior or posteromedial approach is required. If a posterior approach is required the patient should be positioned prone.
- Implant selection: single lateral locking plate or lateral locking and posteromedial plate.
- The surgeon should consider whether a nonsterile or sterile tourniquet is required.
- Imaging: The C-arm should be placed on the contralateral side of the patient for the lateral exposure. If the surgeon will start with the posteromedial exposure, the C-arm is on the ipsilateral side of the patient. The monitor is positioned for comfortable viewing, usually toward the head of the bed.
- The surgeon should consider a staged protocol with provisional spanning external fixation for high-energy bicondylar injuries with significant soft tissue swelling. Open reduction and internal fixation can be done when swelling has subsided.

FIG 4 • Supine positioning for fixation of bicondylar tibial plateau fractures should provide for unhindered AP and lateral fluoroscopic radiographs and both medial and lateral approaches.

Positioning

- The patient is placed supine with the contralateral limb secured to a radiolucent or fracture table, with a bump under the ipsilateral hip (removed for medial approach) (FIG 4).
- Nonsterile high thigh tourniquet
- C-arm on contralateral side with the monitor near the head of the bed

Approach

- A midline approach with medial and lateral exposure has been associated with high complication rates and should be avoided.
  - When medial and lateral exposure is required, an anterolateral exposure with the addition of a posteromedial approach is therefore preferred.
- An anterolateral approach is the standard approach for most tibial bicondylar fractures. It allows for direct exposure of lateral meniscus and intra-articular fractures and for placement of lateral plates.
  - Metaphyseal fracture components are best treated indirectly, especially when comminuted, to maximally preserve biologic potential for healing.
  - The medial condyle can be stabilized with lateral locking plates, provided multiple locking screws engage the medial fragment.
- Bicondylar fractures with displaced medial articular involvement require more direct reduction and stabilization, usually via a posteromedial exposure.
- Soft tissue dissection should be limited with a dual incision technique.
- A minority of fractures, those with a bicondylar posterior shearing injury pattern, may benefit from a direct posterior exposure.

POSTEROMEDIAL APPROACH

- The incision is started 1 cm posterior to the posteromedial edge of the tibial metaphysis (TECH FIG 1A).
  - The saphenous vein and nerve should be carefully avoided during the superficial dissection.
  - Deep dissection continues to expose the pes anserine tendons (TECH FIG 1B), which can be mobilized anteriorly and posteriorly.
  - If more proximal extension of the incision is needed, the surgeon can proceed posterior and parallel to the pes anserine tendons.
- The medial gastrocnemius is easily dissected from the posteromedial tibia.
- Subperiosteal dissection should be limited to the fracture margins to aid in confirmation of the reduction.
- The plate should be slightly undercontoured to help buttress the posteromedial fragment (TECH FIG 1C,D).
LATERAL EXPOSURE

- The surgeon identifies and marks landmarks (tubercle of Gerdy, tibial crest, patella, fibular head).
- The lower extremity is exsanguinated and the tourniquet inflated to about 300 mm Hg.
  - Tourniquet use is optional.
- The skin incision is marked. The incision should begin distally about 2 cm lateral to the tibial crest, curving over the tubercle of Gerdy, then proceeding superiorly over the femoral epicondyle (TECH FIG 2A).
- The skin incision is marked. The incision should begin distally about 2 cm lateral to the tibial crest, curving over the tubercle of Gerdy, then proceeding superiorly over the femoral epicondyle (TECH FIG 2B).
- The skin is incised along the marked incision. The surgeon sharply dissects to fascia without detaching subcutaneous fat from the fascia (TECH FIG 2C).
- The iliobial band is split longitudinally parallel to the skin incision without disrupting the capsule (TECH FIG 2D).
- The iliobial band is elevated from the tubercle of Gerdy anteriorly and posteriorly.
- If required for lateral articular reduction, a lateral submensical arthrotomy is made by incising the capsule horizontally, including the coronary ligament (TECH FIG 2D).
- The meniscus is elevated and inspected for tears.
- The surgeon directly visualizes intra-articular fracture fragments laterally and obtains reduction.
- The metaphyseal fractures should be indirectly reduced with fluoroscopic guidance.
- Preliminary reduction may be held with Kirschner wire fixation or a large periarticular reduction forcep.
- Simultaneous exposure of the medial side may be required if medial reduction is not obtained by indirect methods.
**FIXATION**

- A laterally applied plate is useful to support lateral split fragments and to support depressed articular fragments (via the raft effect of multiple proximal screws placed subchondrally).
- Support of the medial side can be provided via a lateral plate when the medial fragment is of sufficient size and location that multiple screws from the lateral plate engage the medial fragment (TECH FIG 3).
- Locking screws provide superior resistance to medial subsidence and are preferred to nonlocking screws for this application.

- D. Submensical arthrotomy provides direct access to the lateral articular surface.

**TECH FIG 3**

- Bicondylar tibial plateau fracture. Preoperative AP (A) and lateral (B) radiographs and CT scan (C). 
(continued)
An S-shaped incision starts midline superiorly and extends medial distally. The incision is centered on the popliteal fossa, with the transverse component made at the joint line (TECH FIG 4A,B). The surgeon identifies and protects the common peroneal nerve, popliteal artery and vein, tibial nerve, and medial sural cutaneous nerve (TECH FIG 4C).

Full-thickness fasciocutaneous flaps are raised.

The lateral head of the gastrocnemius is dissected bluntly and its blood supply protected distally. The tendon is divided proximally, leaving a stump for repair.

The lateral gastrocnemius is retracted medially (TECH FIG 4D). The popliteus and soleus origin are elevated off the posteromedial aspect of the proximal tibia.

The articular surface is elevated through the fracture site and the reduction assessed with fluoroscopy.

A 3.5-mm plate is contoured to buttress the fragments. Lag screw technique is used to compress the fragments (TECH FIG 4E,F).

When compression is required between the medial and lateral fragment, nonlocked lag screws should be used before placing locked screws across the fracture line.

When the medial fragment is of such size and location that multiple locked screws from a lateral plate cannot engage this fragment, separate medial fixation is required.

This is most commonly the case with posterior medial fragments that are amenable to separate posteromedial buttress plate fixation.

Subchondral defects should be grafted with allograft, autograft, or bone substitute.

It may be helpful in some cases to use allograft bone croutons to help reduce depressed fracture fragments by impacting the graft through a cortical window inferior to the articular surface.

A tamp is used to impact the graft along the inferior surface of the depressed fragment and elevate the fragment to its proper position.

Once the articular surface has been reduced and final fixation achieved, then the meniscus may be repaired if needed.

Most of the meniscal injuries are peripheral rim tears and may be repaired in a horizontal mattress fashion to the capsule.

Layered closure of the lateral wound is done with a lateral drain.

Subchondral defects should be grafted with allograft, autograft, or bone substitute.

POSTERIOR APPROACH (POSTERIOR SHEARING FRACTURE)
PEARLS AND PITFALLS

Do not rely on a lateral locked plate to prevent varus collapse of bicondylar fractures with posteromedial articular components.

Posteromedial intra-articular tibial fragments need buttress plates to prevent varus collapse even with newer locking plate technology.

When the medial fragment is of such size and location that multiple locked screws from a lateral plate cannot engage this fragment, separate medial fixation is required. This is most commonly the case with posterior medial fragments that are amenable to separate posteromedial buttress plate fixation.

Failure to recognize meniscal injury and repair.

- A laterally applied plate is useful to support lateral split fragments (via buttress effect) and to support depressed articular fragments (via a raft effect of multiple proximal screws placed subchondrally).

- Support of the medial side can be provided via a lateral plate when the medial fragment is of such a size and location that multiple screws from the lateral plate engage the medial fragment. Locking screws provide superior resistance to medial subsidence and are preferred to nonlocking screws for this application.

- When compression is required between the medial and lateral fragments, nonlocked screws should be used before placing locked screws across the fracture site.
POSTOPERATIVE CARE

- Use of a continuous passive motion (CPM) device should be started immediately after surgery at about 0 to 40 degrees. Flexion is advanced 5 to 10 degrees during each of three 2-hour sessions per day, with the goal being 0 to 90 degrees before hospital discharge.
- Deep vein thrombosis prophylaxis is considered with low-molecular-weight heparin, aspirin, or Coumadin and a sequential compression device on the contralateral limb.
- Initial home physical therapy concentrates on restoring range of motion with closed-chain active range-of-motion exercises.
- Toe-touch weight bearing is permitted for 6 to 12 weeks depending on radiographic and clinical healing response.
- Weight bearing is advanced and strengthening exercises are initiated upon fracture healing, usually about 8 to 12 weeks postoperatively.

OUTCOMES

- Satisfactory articular reduction (step-off or gap of 2 mm or less) in 62.1% of cases
  - 91.2% had satisfactory coronal plane alignment
  - 72.1% had satisfactory sagittal plane alignment
- According to Barei et al., bicondylar tibial plateau fractures have a significant negative effect on leisure activities, employment, and general mobilization. Significant residual dysfunction was observed out to 51 months postoperatively when compared with the general population.
- Decreased arc of motion compared to the uninvolved extremity

COMPLICATIONS

- Compartment syndrome
- Infection (7% to 8.4%)
- Superficial and deep wound complications
- Residual knee joint instability
- Removal of hardware due to local discomfort
- Deep vein thrombosis
- Arthrosis
- Loss of motion

REFERENCES

Tibial plateau fractures are intra-articular fractures that may result in a malalignment of the articular surface and bear the risk of subsequent arthritis.

The lateral plateau is smaller and convex, whereas the medial plateau is larger and slightly concave. Both plateaus are covered by a meniscus, which serves as a shock absorber and improves the congruency of the femorotibial joint. The lateral plateau sits slightly higher than the medial joint surface, forming an angle of 3 degrees of varus with respect of the tibial shaft. This is helpful in identifying the lateral plateau on the lateral radiograph.

The anatomy of the tibial plateau leads to an eccentric load distribution in which the lateral plateau bears 40% of the knee’s load. This asymmetric weight bearing results in increased medial subchondral bone formation and a stronger, denser medial plateau.

The intermediate, nonarticular intercondylar eminence serves as the tibial attachment of the anterior and posterior cruciate ligaments.

The stability of the knee joint is based on the cruciate ligaments, the collateral ligaments, and the capsule.

The intermediate, nonarticular intercondylar eminence serves as the tibial attachment of the anterior and posterior cruciate ligaments.

The stability of the knee joint is based on the cruciate ligaments, the collateral ligaments, and the capsule.

The lateral plateau sits slightly higher than the medial plateau and may be associated with complex tibial plateau fractures.

The most frequent mechanism causing a lateral plateau fracture is a direct trauma to the proximal tibia and knee joint. This induces a valgus force and drives the lateral femoral condyle into the soft lateral tibial plateau.

Indirect axial forces often develop in high-energy injuries and may be associated with complex tibial plateau fractures.

Twisting injuries account for only 5% to 10% of tibial plateau fractures and are most commonly sports injuries (eg, skiing).

DEFINITION

■ Tibial plateau fractures are intra-articular fractures that may result in a malalignment of the articular surface and bear the risk of subsequent arthritis.

ANATOMY

■ The tibial plateau consists of three osseous structures: the lateral plateau, the medial plateau, and the intercondylar eminence.

■ The lateral plateau is smaller and convex, whereas the medial plateau is larger and slightly concave. Both plateaus are covered by a meniscus, which serves as a shock absorber and improves the congruency of the femorotibial joint.

■ The lateral plateau sits slightly higher than the medial joint surface, forming an angle of 3 degrees of varus with respect of the tibial shaft. This is helpful in identifying the lateral plateau on the lateral radiograph.

■ The anatomy of the tibial plateau leads to an eccentric load distribution in which the lateral plateau bears 40% of the knee’s load. This asymmetric weight bearing results in increased medial subchondral bone formation and a stronger, denser medial plateau.

■ The intermediate, nonarticular intercondylar eminence serves as the tibial attachment of the anterior and posterior cruciate ligaments.

■ The stability of the knee joint is based on the cruciate ligaments, the collateral ligaments, and the capsule.

■ The tibial tuberosity and the tubercle of Gerdy are bony prominences located in the subcondylar region for insertion of the patellar tendon and the iliotibial tract, respectively. These landmarks are important for planning surgical incisions.

PATHOGENESIS

■ Several anatomic factors have been thought to contribute to the higher incidence of lateral as opposed to medial plateau fractures.

■ The relative softness of the subchondral bone of the lateral plateau, the valgus axis of the lower extremity, and the susceptibility of the leg to a medially directed force all lead to a prevalence of lateral plateau fractures in low-energy injuries.

■ Tibial plateau fractures are due to either direct trauma to the proximal tibia and knee joint or to indirect axial forces.

■ The most frequent mechanism causing a lateral plateau fracture is a direct trauma to the proximal tibia and knee joint. This induces a valgus force and drives the lateral femoral condyle into the soft lateral tibial plateau.

■ Indirect axial forces often develop in high-energy injuries and may be associated with complex tibial plateau fractures.

■ Twisting injuries account for only 5% to 10% of tibial plateau fractures and are most commonly sports injuries (eg, skiing).

■ Split or wedge fractures occur in younger patients, whereas depression fractures occur more frequently in older patients with osteoporotic bone, which is less able to withstand compression.

NATURAL HISTORY

■ The natural history of lateral tibial plateau fractures depends on the degree of articular depression and knee stability. Knee instability may result from the fracture itself but may also result from accompanying injuries like meniscal injuries or rupture of cruciate or collateral ligaments.

■ For nondisplaced or minimally displaced fractures, the prognosis is favorable, but displaced fractures, especially in combination with knee instability, tend to result in early posttraumatic arthritis.

■ Meniscal injuries have been reported in up to 50% of tibial plateau fractures. Meniscal injuries are a major determinant of prognosis because meniscal integrity is important for joint stability and may compensate for articular incongruity.

PATIENT HISTORY AND PHYSICAL FINDINGS

■ The physical examination should always include a thorough assessment of the soft tissue envelope.

■ The marginal soft tissue envelope of the proximal tibia predisposes to open fractures and development of tissue necrosis. It is important to assess severe soft tissue injury because it may not allow primary plating of the fracture, requiring external fixation.

■ A compartment syndrome may result from continuous hemorrhage through the metaphysis into the area of the tibial shaft.

■ Clinical findings indicating a manifest compartment syndrome include pain, paresthesia, paresis, pain with stretch, intact pulses, and pink skin coloring.

■ Such findings require immediate fasciotomy.

■ An imminent compartment syndrome requires repeated or continuous compartment pressure monitoring.

■ A pressure difference between the diastolic pressure and the compartment pressure of less than 30 mm Hg is considered to be a manifest compartment syndrome, which requires fasciotomy.

■ The neurovascular status of the extremity must be carefully evaluated, although concomitant injuries of neurovascular structures are rare in proximal tibia fractures.

■ Palpation of peripheral pulses

■ Doppler ultrasound

■ An ankle-brachial index less than 0.9 indicates that vascular injury is very likely.

■ Impaired sensorimotor status may indicate compartment syndrome; impaired dorsal flexion may indicate direct peripheral nerve injury.

■ Examination of knee stability is difficult because of pain, so it should be tested under anesthesia. Assessment of knee stability may be difficult on initial examination because of continuous compartment pressure monitoring.
intracapsular hematoma and pain. Varus and valgus stress radiographs of the knee in near-full extension can be performed with sedation or under general anesthesia. Widening of the femoral–tibial articulation of more than 10 degrees indicates ligamentous insufficiency.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain anteroposterior (AP) and lateral radiographs should be centered on the knee, with the AP view angled 10 degrees in a cranio-caudal direction to approximate the posterior slope of the plateau.
- The standard tool in analyzing tibial plateau fractures is the three-dimensional CT scan, because the number and degree of isolated fractures are often underestimated on plain radiographs.\(^{13}\)
- Although MRI evaluates both osseous and soft tissue injuries, it has not yet become a standard tool in analyzing tibial plateau fractures. It may be helpful in identifying meniscal and ligamentous injuries.
- In selected cases (eg, no CT diagnostics available), stress radiographs may be helpful in making decisions about surgical management.

**DIFFERENTIAL DIAGNOSIS**
- Ligamentous injuries of the knee
- Knee dislocation
- Meniscal injury
- Bone bruise
- Compartment syndrome

**NONOPERATIVE MANAGEMENT**
- For nondisplaced or minimally displaced fractures, the indications for surgical treatment are controversial and vary widely in the literature. The range of acceptability for articular depression varies from 2 mm to 1 cm.\(^{3,5,6,17,19,22}\)
- Nondisplaced or minimally displaced tibial plateau fractures with stability of the knee joint can be managed nonoperatively, provided that the patient is compliant.
- Partial weight bearing in a hinged fracture brace for 8 to 12 weeks with regular radiographic controls is recommended.
- Isometric quadriiceps exercises and progressive passive, active-assisted, and active range-of-knee motion exercises are recommended to avoid substantial muscle atrophy.
- Failure to maintain reduction with nonoperative management is an indication for surgical fracture stabilization. Therefore, frequent surveillance radiographs are required for the management of these patients.

**SURGICAL MANAGEMENT**
- The primary management of tibial plateau fractures is usually dictated by the soft tissue injury and by the fracture type.
- Absolute indications for surgery are displaced fractures, open fractures, fractures with vascular or neurologic lesions, fractures with compartment syndrome, and fractures with valgus instability.
- The goals in the surgical treatment of tibial plateau fractures are restoration of articular surface, axis, meniscal integrity, and stability to avoid or postpone posttraumatic arthritis. Fracture stability allows early rehabilitation and supports long-term full recovery.
- The degree of soft tissue injury and the general condition of the patient are important factors in surgical decision making.
- If there is severe soft tissue damage, an open fracture, or a polytraumatized patient, a temporary external fixator is applied. Definitive fracture stabilization with open reduction and internal fixation is delayed until soft tissue damage or the patient’s critical condition has been resolved.

**Preoperative Planning**
- Review of radiographs, CT, MRI
- Surgical approach and placement of implants
- Depression fractures with continuity of the lateral cortex require only screw osteosynthesis.
- Whether a cortical window is required depends on the degree and location of impaction. Condylar widening is a good radiologic sign for the requirement of articular elevation with a pestle via a cortical window.
- Meniscal and ligamentous injuries require open joint or arthroscopic surgery.
- The surgeon should consider the need of bone grafting (iliac crest bone graft, bone graft substitute) when severe depression of the plateau is obvious.
- For surgical decision making, a separate classification of the fracture and degree of soft tissue injury is important.
- Open fractures are classified according to Gustilo et al.\(^{4}\)
- The soft tissue injury is classified according to Tscherne and Oestern.\(^{21}\)
- The AO/OTA classification for proximal tibial fractures distinguishes between extra-articular, partial-articular, and complete-articular fractures, and further subdivides based on the level of comminution (Table 1).
- Schatzker’s classification distinguishes between lateral and medial plateau fractures (Table 2).
- In general, types I through III are low-energy injuries affecting the lateral plateau.
- Types IV through VI involve increasingly higher-energy injuries mostly affecting the medial plateau in combination with ligamentous injuries.\(^{19}\)

**Positioning**
- Supine position
- Bolster under knee to improve internal rotation: the knee should be slightly bent (about 30 degrees) to reduce tension of collateral ligaments (FIG 1)

- Tourniquet to minimize blood loss and to improve fracture visualization
- Radiolucent operating table to allow intraoperative use of fluoroscopy and image intensification
- Contralateral leg placed in leg carrier
- Ipsilateral iliac crest is prepared and draped if bone graft is needed.

**Approach**
- The surgical approach for lateral tibial plateau fractures demands good visualization of the lateral plateau, combined with preservation of all anatomic structures and minimal soft tissue and osseous devitalization. It can be summarized as:
  - Elevation of the meniscus
  - Reduction of the fracture
  - Temporary retention with Kirschner wire or small fragment lag screw
  - Final stabilization with lag screws, conventional plate, or angular stable plate
- The incision must be planned to avoid implant location directly underneath the skin incision. Important landmarks are the joint line, the tubercle of Gerdy, the tibial tubercle, the fibula head, and the lateral femoral epicondyle (FIG 2).
- The standard approach for lateral tibial plateau fractures is the anterolateral approach, which provides excellent exposure of the lateral plateau and allows good soft tissue coverage of the implant, especially after minimally invasive plate application.
- The posterolateral approach is indicated for fractures of the lateral posterior plateau.

**ANTEROLATERAL APPROACH**
- A straight or a hockey-stick incision (about 10 cm) with the knee in 30 degrees of flexion is made.
- The incision is extended down through the iliobial band proximally and the fascia of the anterior compartment distally.
- The tibialis anterior muscle is elevated off the proximal tibia to the level of the capsule and the coronary ligament is incised (TECH FIG 1).
- To expose the lateral tibial plateau, the lateral meniscus is raised with holding sutures after incision of the coronary ligament.
- The size of the fragment is crucial for the decision of whether soft tissue is stripped off. For small fragments not allowing compression, stripping the displaced fragment for buttress plating is indicated.
POSTEROLATERAL APPROACH
- A longitudinal incision is made along the proximal fibula (TECH FIG 2).
- The extensor muscles are mobilized from the tibial plateau.
- After exposure of the peroneus nerve, osteotomy of fibula head is performed.
- At the end of surgery the fibular head is refixed by tension band wiring or screw fixation.

REDUCTION
- Careful treatment of soft tissue and periosteum is mandatory.
- Reduction is aided by ligamentotaxis and careful manipulation. An external fixator or a distractor may be a helpful tool.
- Displaced fragments are reduced with reduction tools.
- Reduction is temporarily maintained with Kirschner wires or lag screws (TECH FIG 3).

REDUCTION OF IMPACTED SEGMENTS
- Impression fractures need to be elevated with a pestle, which may be inserted through a distal tibial bone window (TECH FIG 4).
- Elevation is achieved by carefully exerting punches on the pestle (eg, with a hammer) under fluoroscopy until the contour of the articular surface is re-established.
- In cases of severe bone loss, the defect must be filled with bone graft or bone substitute.
MENISCAL REPAIR

- Meniscal integrity is important for stability and to avoid posttraumatic arthritis.
- Peripheral longitudinal lesions of the anterior and intermediate part of the meniscus are fixated using the “outside-in suture” technique.
- Peripheral longitudinal lesions of the posterior meniscus are fixated using the “all-inside” technique to avoid injury to the neurovascular structures in the popliteal area.
- Complex meniscal lesions in the avascular area require resection.

OSTEOSYNTHESIS

Implants

- Implants may include cancellous screws, conventional plates, or, most recently, angular stable plates.
- If the lateral metaphyseal shell is intact, a lag screw with a washer or a three-hole conventional plate in the antiglide position is usually sufficient.
- Multifragmentary fractures or fractures with severe bone loss usually require plate osteosynthesis.
- Prefomed locking or nonlocking plates allow an exact alignment and retention of the fracture.
- A minimally invasive technique by sliding the plate with the aiming device underneath the muscle may be selected. The screws can be applied by stitch incisions.

Pure Split Fractures of the Lateral Plateau (AO-41-B1 or Schatzker I)

- For fixation, two large partially threaded cancellous bone screws with washers can be used (TECH FIG 5).

Locking Plates

- In multifragmentary fractures or fractures with severe bone loss, an evidence-based advantage of locking plates versus nonlocking plates has not been reported in the literature.
- However, locking plates in these types of plateau fractures are advisable for the following reasons:
  - Angular stable plates require less bone graft compared to conventional plates in fractures with severe bone loss.
  - The stability of angular stable plates does not depend on friction between the plate and the bone, so less compression of the periosteum, with consequent better blood supply to the fracture area, is achieved.
PEARLS AND PITFALLS

Meniscal repair

- Meniscal repair is crucial to reduce the incidence of degenerative changes after tibial plateau fractures. Even a failed meniscal repair that requires subsequent meniscectomy can be briefly protective to the underlying cartilage.\(^{19}\)

Articular depression

- Articular depression is a major determinant of posttraumatic arthritis. After surgical management, no articular depression should be obvious. However, secondary articular depression may occur due to loss of fixation. To prevent secondary articular depression, sufficient bone graft or bone graft substitute should be used to stabilize tibial plateau depression fractures. However, tibial plateau depression fractures with a poor radiographic reconstruction may still be associated with a good functional outcome if meniscal integrity is preserved.
- Excessive soft tissue stripping may increase the risk for infection and nonunion. Therefore, minimally invasive techniques with the least possible soft tissue stripping and soft tissue irritation should be used.

Bone grafting

- Iliac crest bone grafting is the treatment of choice to maintain the reduction of depressed tibial plateau fragments. Bone substitutes such as coralline hydroxyapatite and calcium-phosphate cements have also been successfully used.

Soft tissue assessment

- Soft tissue assessment is an easy but pivotal step in the management of tibial plateau fractures. An excellent reduction and fixation may be compromised by infection secondary to inadequate assessment of the surrounding soft tissue status. Fractures with severe soft tissue impairment benefit from external stabilization and secondary open reduction and internal fixation.

Pure Depression Fractures of the Lateral Plateau (AO-41-B2 or Schatzker III)

- The depression is elevated through a cortical window and stabilized with two subchondral cancellous bone screws. In cases of severe bone loss, bone graft or bone graft substitute may also be needed for stabilization.
- In osteopenic patients, a third cancellous bone screw with washer is recommended in an antiglide position, whereas in case of fragmentation a lateral buttress plate is used (TECH FIG 6).

Split-Depression Fracture of the Lateral Plateau (AO-41-B3 or Schatzker II)

- The depression is elevated by working through the split component and deposition of bone graft (TECH FIG 7).
- Three position screws are placed subchondrally to support the impacted joint surface (rafting) and a locking plate or buttress plate is applied.

TECH FIG 7 • Stabilization of B3 or Schatzker II fracture with buttress plate.
POSTOPERATIVE CARE

- Rehabilitation must be planned individually and depends on patient age, bone quality, type of osteosynthesis, and concomitant injury.
- Ninety degrees of flexion should be achieved by 7 to 10 days.
- Toe-touch weight bearing is recommended for 4 to 8 weeks, with progression thereafter according to radiographic findings.
- Impression fractures of the lateral plateau managed with a minimally invasive angular plate are allowed weight bearing about 12 weeks after surgery.
- Early mobilization and range-of-motion exercises are key to the successful treatment of proximal tibia fractures to avoid later knee stiffness and muscle wasting.

OUTCOMES

- The outcome depends mostly on knee stability, joint congruity, meniscal integrity, and correct axis.
- A favorable outcome has been reported for surgically treated low-energy tibial plateau fractures. For split and split-depression fractures, adequate surgical techniques yield more than 90% good and excellent results.
- However, concomitant injuries of ligaments and menisci can compromise the outcome. Therefore, maintaining menisci and ligamentous stability is important.
- Satisfactory functional results can be obtained in the face of poor radiographic results, however, and may be due to preservation of the meniscus and its ability to bear the load of the lateral compartment.
- The incidence of wound infection appears to correlate with the amount of hardware implanted and ranges from 0% to 32% for fractures managed with the buttress technique.
- Deep vein thrombosis rates are reported to be 5% to 10%, and pulmonary embolus occurs in 1% to 2% of patients.
- Late complications:
  - Loss of fixation with axial malalignment and valgus deformity
  - Malunion as a consequence of inadequate reduction or loss of reduction
  - Posttraumatic arthrosis, which may result from the initial chondral damage or may be related to residual joint incongruity

REFERENCES

DEFINITION

- Indications for external fixation of the tibial shaft in trauma applications include the treatment of open fractures with extensive soft tissue devitalization and contamination. Other indications include the stabilization of closed fractures with high-grade soft tissue injury or compartment syndrome.
- For patients with multiple long bone fractures, external fixation has been used as a method for temporary, if not definitive, stabilization.
- With the introduction of circular and hybrid techniques, indications have been expanded to include the definitive treatment of complex periarticular injuries, which include high-energy tibial plateau and distal tibial pilon fractures.
- Contemporary external fixation systems in current clinical use can be categorized according to the type of bone anchor used.
- This is achieved either using large threaded pins, which are screwed into the bone, or by drilling small-diameter transfixion wires through the bone. The pins or wires are then connected to one another through the use of longitudinal bars or circular rings.
- The distinction is thus between monolateral external fixation (longitudinal connecting bars) and circular external fixation (wires connecting to rings).
- Acute trauma applications primarily use monolateral frame configurations and are the focus of techniques described here.
- The first type of monolateral frame comes with individual separate components: separate bars, attachable pin–bar clamps, bar-to-bar clamps, and Schanz pins (FIG 1A). These “simple monolateral” frames allow for a wide range of flexibility with “build-up” or “build-down” capabilities.
- The second type of monolateral frame is a more constrained type of fixator that comes preassembled with a multipin clamp at each end of a long rigid tubular body. The telescoping tube allows for axial compression or distraction of this so-called monotube-type fixator (FIG 1B).
- For diaphyseal injuries, the most common type of fixator application is the monolateral type of frame using large pins.
- Simple monolateral fixators have the distinct advantage of allowing individual pins to be placed at different angles and varying obliquities while still connecting to the bar. This is helpful when altering the pin position avoid areas of soft tissue compromise (ie, open wounds or severe contusion).
- The advantage of the monotube-type fixator is its simplicity. Pin placement is predetermined by the multipin clamps. Loosening the universal articulations between the body and the clamps allows these frames to be easily manipulated to reduce a fracture.
- Many high-energy fractures involve the metaphyseal regions, and transfixion techniques using small tensioned wires are ideally suited to this region. They have better mechanical stability and longevity than traditional half-pin techniques.
- Small tensioned wire circular frames or hybrid frames can be useful in patients with severe tibial metaphyseal injuries that occur in concert with other conditions such as soft tissue compromise or compartment syndrome, or in patients with multiple injuries (FIG 1C,D).

ANATOMY

- The bulk of the tibia is easily accessible in that most of the diaphyseal portion is subcutaneous.
- Also, the hard cortical bone found in this location is ideally suited to the placement of large Schanz pins, which achieves excellent mechanical fixation.
- The cross-sectional anatomy of the diaphysis and the lateral location of the muscular compartments allow placement of half-pins in a wide range of subcutaneous locations. This facilitates pin placement “out of plane” to each other, which helps achieve overall frame stability (FIG 2).
- The proximal and distal periarticular metaphyseal regions of the tibia are also subcutaneous except for their lateral surfaces. The bone in these locations is primarily cancellous, with thin cortical walls.
- The mechanical stability achieved with half-pins depends on cortical purchase and therefore may not be adequate for fixation in this cortex-deficient region.
- Excellent stability is afforded in these areas by using small-diameter tensioned transfixion wires in conjunction with circular external fixators.

PATHOGENESIS

- Open tibial diaphyseal fractures are primarily candidates for closed intramedullary nailing, but there are occasions when external fixation is indicated.
- External fixation is favored when there is significant contamination and severe soft tissue injury or when the fracture configuration extends into the metaphyseal–diaphyseal junction or the joint itself, making intramedullary nailing problematic.
- The choice of external fixator type depends on the location and complexity of the fracture, as well as the type of wound present when dealing with open injuries.
- The less stable the fracture pattern (ie, the more comminution), the more complex a frame needs to be applied to control motion at the bone ends.
- If possible, weight bearing should be a consideration.
- If periarticular extension or involvement is present, the ability to bridge the joint with the frame provides satisfactory stability for both hard and soft tissues.
- It is important that the frame be constructed and applied to allow for multiple débridesments and subsequent soft tissue reconstruction. This demands that the pins are placed away from the zone of injury to avoid potential pin site contamination with the operative field.
Fractures treated with external fixation heal with external bridging callus. External bridging callus is largely under the control of mechanical and other humoral factors and is highly dependent on the integrity of the surrounding soft tissue envelope. This type of fracture healing has the ability to bridge large gaps and is very tolerant of movement.

- Micromotion with the external fixator construct has been found to accentuate fracture union. It results in the development of a large callus with formation of cartilage due to the greater inflammatory response caused by increased micromovement of the fragments.
- There appears to be a threshold at which the degree of micromotion becomes inhibitory to this overall remodeling process, however, so hypertrophic nonunion can result from an unstable external frame.

- Temporary spanning fixation for complex articular injuries is used routinely. The ability to achieve an initial ligamentotaxis reduction substantially decreases the amount of injury-related swelling and edema by reducing large fracture gaps.
- It is important to achieve an early ligamentotaxis reduction: a delay of more than a few days will result in an inability to disimpact displaced metaphyseal fragments.
- Once the soft tissues have recovered, formal open reduction and internal fixation can be accomplished with relative ease as the operative tactic can be directed to the area of articular involvement.
- Application of these techniques in a polytrauma patient is valuable when rapid stabilization is necessary for a patient in extremis. Simple monolateral or monotube fixators can be placed rapidly across long bone injuries, providing adequate...
stabilization to facilitate the management and resuscitation of the polytrauma patient (FIG 3).

**NATURAL HISTORY**

- The stability of all monolateral fixators is based on the concept of a simple “four-pin frame.”
- Pin number, pin separation, and pin proximity to the fracture site, as well as bone bar distance and the diameter of the pins and connecting bars, all influence the final mechanical stability of the external fixator frame.
- Large pin monolateral fixators rely on stiff pins for frame stability. On loading, these pins act as cantilevers and produce eccentric loading characteristics. Shear forces are regarded as inhibitory to fracture healing and bone formation, and this may be accentuated with pins placed in all the same orientation.
- After stable frame application, the soft tissue injury can be addressed. Once the soft tissues have healed, conversion to definitive internal fixation can be safely accomplished. In some cases the external device is the definitive treatment. Dynamic
weight bearing is initiated at an early stage once the fracture is deemed stable.

- In fractures that are highly comminuted, weight bearing is delayed until visible callus is achieved and sufficient stability has been maintained. As healing progresses, active dynamization of the frame may be required to achieve solid union.
- Dynamization converts a static fixator, which seeks to neutralize all forces including axial motion, and allows the passage of forces across the fracture site. As the elasticity of the callus decreases, bone stiffness and strength increase and larger loads can be supported. Thus, axial dynamization helps to restore cortical contact and to produce a stable fracture pattern with inherent mechanical support. This is accomplished by making adjustments in the pin–bar clamps with simple monolateral fixators or in releasing the body on a monotube-type fixator.
- Bony healing is not complete until remodeling of the fracture has been achieved. At this stage, the visible fracture lines in the callus decrease and subsequently disappear. The fixator can be removed at this point.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- History should focus on the mechanism of injury.
- Determining whether the injury was high energy versus low energy gives the surgeon an idea of the extent of the soft tissue zone of injury and will help determine the possible location of fixation pins.
- Determining the location of the accident is helpful in cases of open fracture (ie, open field with soil contamination vs. slip and fall on ice and snow).
- These parameters give the surgeon an idea as to the extent of intraoperative débridement that might be required to cleanse the wound and the necessary antibiotic coverage for the injury.
- The neurovascular status should be documented, specifically the presence or absence of the anterior and posterior tibial pulses at the ankle.
- A weak or absent pulse may be an indication of vascular injury and may dictate further evaluation with ankle-brachial indices, compartment pressure evaluation, or a formal arteriogram.
- Evaluation of compartment pressures is often indicated in open fractures and closed high-energy fractures with severe soft tissue contusion.
- Evaluation of soft tissues and grading of the open fracture with regard to the size, orientation, and location of the open wounds aid in decision making about pin placement and the configuration of the fixator to allow access to open wounds (FIG 4).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging of the tibia should include at least two orthogonal views, anteroposterior and lateral.
- Radiographs of the knee and ankle are necessary to evaluate any articular fracture involvement or associated knee or ankle subluxation or dislocation.
- Identifying any occult fracture lines aids in the preoperative planning of potential pin placement.
- Many patients with high-energy tibial fractures have associated foot injuries, and views of the foot and ankle are necessary to identify this injury pattern.
- Traction radiographs of articular injuries of the tibia are useful to identify the nature and orientation of metaphyseal fragments as well as degree of articular impaction. This aids in determining whether a joint-spanning fixator is necessary.
- Distraction CT scans should be obtained after the knee- or ankle-spanning fixator has been applied. These studies indicate the effectiveness of the ligamentotaxis reduction. This allows the surgeon to determine the preoperative plan for definitive fixation once the soft tissues have recovered (FIG 5).

**SURGICAL MANAGEMENT**

- The surgical decisions relate to the configuration of the external device to be applied. These generally will fall into two categories of treatment options.
- The first category is a temporary device intended to allow the soft tissues to recover or the patient’s overall condition to
improve until definitive fixation of the injury can be safely carried out.

- Temporary frames include knee- or ankle-spanning fixators used in cases of periarticular injuries requiring ligamentotaxis reduction and relative stabilization, and simple frames spanning a tibial shaft fracture in the case of a polytrauma patient who needs emergent stabilization of injuries. These frames are later converted to intramedullary nails once the patient can undergo additional surgery.
- They are simplistic and not intended for long-term treatment times.
- Definitive treatment fixators are primarily applied to diaphyseal injuries with severe soft tissue compromise (open and closed).
- These devices are maintained throughout the entire treatment period to allow access to soft tissues and facilitate secondary procedures such as rotational or free flap coverage as well as delayed bone grafting.
- These frames are more involved and are intended to remain in place for the entire treatment period.

**Preoperative Planning**

- Evaluation of injury radiographs should identify any distal or proximal articular extension into the knee or ankle joint.
- Location of the primary fracture is noted in terms of proximal or distal locations to help decide on a particular fixator construct and to help determine if a joint-spanning fixator is required.

**Positioning**

- The patient’s entire lower extremity is elevated using bumps or a beanbag patient positioner under the ipsilateral hip (FIG 6). This elevates the tibia off the operating table.
The correct insertion technique involves incising the skin directly at the side of pin insertion. After a generous incision is made, dissection is carried directly down to bone and the periosteum is incised where anatomically feasible (TECH FIG 1A). A small Penfield-type elevator is used to gently reflect the periosteum off the bone at the site of insertion (TECH FIG 1B). Extraneous soft tissue tethering and necrosis is avoided by minimizing soft tissue at the site of insertion.

A trocar and drill sleeve are advanced directly to bone, minimizing the amount of soft tissue entrapment that might be encountered during predrilling (TECH FIG 1C,D). A sleeve should also be used if a self-drilling pin is selected. After predrilling, an appropriate-size depth of pin is advanced by hand to achieve bicortical purchase. Any offending soft tissue tethering should be released with a small scalpel (TECH FIG 1E,F).

The foot can be supported with a sterile bump, thus suspending the limb and allowing full 360-degree access and visualization of the limb. Elevating the limb positions the nonoperative leg below the operative limb, which aids in placing out-of-plane pins as well as circular frame components. The image intensifier is positioned opposite the operative leg. This aids in fluoroscopic visualization of the femur and knee, which is important when applying a knee-spanning fixator for a severe tibial plateau fracture.

**Approach**

- The integrity of the pin–bone interface is a critical factor in determining the longevity of an applied external fixation pin.
- Pin insertion technique is important in achieving an infection-free, stable pin–bone interface and thus maintaining frame stability.

**PIN INSERTION TECHNIQUE**

- The correct insertion technique involves incising the skin directly at the side of pin insertion.
- After a generous incision is made, dissection is carried directly down to bone and the periosteum is incised where anatomically feasible (TECH FIG 1A).
- A small Penfield-type elevator is used to gently reflect the periosteum off the bone at the site of insertion (TECH FIG 1B). Extraneous soft tissue tethering and necrosis is avoided by minimizing soft tissue at the site of insertion.
- A trocar and drill sleeve are advanced directly to bone, minimizing the amount of soft tissue entrapment that might be encountered during predrilling (TECH FIG 1C,D). A sleeve should also be used if a self-drilling pin is selected.
- After predrilling, an appropriate-size depth of pin is advanced by hand to achieve bicortical purchase. Any offending soft tissue tethering should be released with a small scalpel (TECH FIG 1E,F).
MONOLATERAL FOUR-PIN FRAME APPLICATION FOR TIBIAL SHAFT FRACTURE

Contemporary simple monolateral fixators have clamps that allow independent adjustments at each pin-bar interface, allowing wide variability in pin placement, which helps to avoid areas of soft tissue compromise.

Because of this feature, simple four-pin placement may be random on either side of the fracture.

Option 1

The initial two pins are first inserted as far away from the fracture line as possible in the proximal fracture segment and as distal as possible in the distal fracture segment (TECH FIG 2A).

A solitary connecting rod is attached close to the bone to increase the rigidity of the system.

Longitudinal traction is applied and a gross reduction is achieved (TECH FIG 2B–F).

The intermediate pins can then be inserted using the pin fixation clamps attached to the rod to act as templates with drill sleeves as guides.

These pins should not encroach on the open wound or severely contused skin in the immediate zone of injury.

TECH FIG 2 • Placement of a simple four-pin monolateral fixator. A. Two pins are placed on either side of the fracture as far from the fracture as possible. A connecting bar is then attached to the two pins (B) and a gradual reduction is performed (C–F). Two pins are then placed as close to the fracture as possible on either side, after longitudinal traction has accomplished a reduction. The inner pins are then attached and the reduction is fine-tuned.
After placement of these two additional pins, the reduction can be achieved with minimal difficulty by additional manipulation of the fracture.

Once satisfactory reduction has been accomplished, the clamps are tightened and reduction is confirmed via fluoroscopy.

**Option 2**

- Alternatively, all the fixation pins can be inserted independent of each other, with two pins proximally and two pins distally (TECH FIG 3).

The two proximal pins are connected to a solitary bar and the distal two pins are connected to a solitary bar.

Both proximal and distal bars are then used as reduction tools to manipulate the fracture into alignment.

Once reduction has been achieved, an additional bar-to-bar construct between the two fixed-pin couples is connected.

Reduction is confirmed under fluoroscopy.

**TECH FIG 3** • Alternative method for simple four-pin monolateral fixator. A, B. Once the bar is attached, two intercalary clamps can be positioned as templates for the placement of the interior pins. C. Final construct after interior pin placement. D. The proximal and distal two pins can be attached to each other by a solitary bar. These bars can then be used as tools to reduce the fracture. E. The two bars are then connected by a solitary bar and the fracture reduction is maintained. F, G. Closed fracture with associated compartment syndrome is reduced and stabilized using a four-pin fixator with a single connecting bar.
MONOTUBE FOUR-PIN FRAME APPLICATION FOR TIBIAL SHAFT FRACTURE

- Use of the large monotube fixators facilitates rapid placement of these devices, with the fixed-pin couple acting as pin templates (TECH FIG 4).
- Two pins are placed through the fixator-pin couple proximal to the fracture. They are inserted parallel to each other at fixed distances set by the pin clamp itself. These are usually oriented along the direct medial or anteromedial face of the tibial shaft.
- Once the pins are inserted, the pin clamp is tightened to secure them in place.

TECH FIG 4 • A. Tibial shaft fracture with displacement. B. Monotube fixator adjusted to length and orientation, with all ball joints and the telescoping central body loosened. C. Proximal two pins applied using pin couple as template. D. Distal pins inserted and fracture reduced with all ball joints locked to maintain reduction. Telescoping body is also locked to maintain axial alignment. E,F. Injury and reduction radiographs using a large-body monotube fixator for an open comminuted tibial shaft fracture.
- The monotube body is then attached to the proximal pin couple and longitudinal traction applied to achieve a “gross” reduction. The fixator body and distal multipin clamp are oriented along the shaft of the tibia.
- The proximal and distal ball joints should be freely movable with the telescoping body extended.
- Two pins are placed through the pin couple distal to the fracture and tightened.
- Care must be taken to allow adequate length of the monotube frame before final reduction and tightening of the body.
- Using the proximal and distal pin clamps as reduction aids, the fracture is manually reduced. The proximal and distal ball joints are then tightened, accomplishing a reduction.
- At this point, the telescoping body can be extended or compressed to dial in the axial alignment. When length is achieved, the body component is tightened to maintain axial length.
- Monotube bodies have a very large diameter, which limits the amount of shearing, torsional, and bending movements of the fixation construct.
- Axial compression is achieved by releasing the telescoping mechanism.
- Dynamic weight bearing is initiated at an early stage once the fracture is deemed stable.
- In fractures that are highly comminuted, weight bearing is delayed until visible callus is achieved and sufficient stability has been maintained.
- The telescopic body allows dynamic movement in an axial direction, which is a stimulus for early periosteal healing.

**KNEE-SPANNING FIXATOR OF TIBIAL PLATEAU FRACTURE**

- Two Schanz pins are placed along the anterolateral thigh. These pins are placed in the midshaft region of the femur (TECH FIG 5).
- Two Schanz pins are then inserted into the midshaft and distal tibia.

- Apply the tibial pins far enough away from the distal extension of the proximal tibia such that any future incisions required to perform definitive open reduction and internal fixation of the plateau fracture would not impinge on the pins.

**TECH FIG 5 • A,B.** Open tibial plateau stabilized with knee-spanning fixator. Two pins each above (distal femur) and below (midtibia) the fracture are applied. Two bars connect each pin couple. Long connecting bars are then used to connect each pin couple, maintaining the reduced fracture. **C,D.** One single bar connects the two pins proximal to the plateau fracture and the two pins distal to the fracture.
- A solitary bar can then be used to span all pins.
  - Longitudinal traction is applied and reduction confirmed under fluoroscopy.
  - Slight flexion of the knee is maintained and all connections are tightened to maintain the ligamentotaxis reduction.
  - Alternatively, the proximal two femur pins can be connected using a single bar and the two tibial pins with a second bar. These two bars can then be manipulated to achieve a reduction of the plateau, and a third bar connecting the proximal femoral and distal tibial bars is then attached and tightened to maintain the reduction.
  - A large monotube fixator can also be used in this fashion to span the knee and maintain a temporary reduction.

**ANKLE-SPANNING FIXATOR FOR TIBIAL PILON FRACTURE**
- Two Schanz pins are placed into the midshaft tibial region (TECH FIG 6).
  - Avoid any compromised soft tissues and possible fracture extension if spanning the ankle for a severe pilon fracture with shaft extension.
  - A centrally threaded transfixion pin is then placed through the calcaneal tuberosity from medial to lateral, avoiding the posterior tibial artery.
  - The appropriate location for this pin is 1.5 cm anterior to the posterior aspect of the heel and 1.5 cm proximal to the plantar aspect of the heel.
  - This location is confirmed via fluoroscopy.
- A solitary bar is connected to the tibial pins.
  - Medial and lateral bars are then connected to each side of the heel pin, making a triangular configuration.
  - Longitudinal traction is carried out to obtain length, and care is taken to achieve appropriate anteroposterior reduction.
  - To maintain a plantigrade foot and to maintain alignment, a pin is placed into the base of the first or second metatarsal.
  - This forefoot pin is then connected to the main frame with a connecting bar and the foot is held in neutral dorsiflexion.

**TECH FIG 6 • Ankle-spanning fixators bridging severe pilon fractures.**
- A. Two pins are placed into the distal tibia, proximal enough to be out of the zone of injury. A calcaneal transfixion pin is placed through the calcaneal tuberosity and subsequent medial-lateral triangulation connecting bars are attached. Longitudinal traction is applied and all bars are tightened to maintain reduction. B,C. A forefoot pin is placed into the second metatarsal to maintain the foot in a neutral position and avoid equinus contracture.

**TWO-PIN FIXATOR: TEMPORARY STABILIZATION FOR TIBIAL SHAFT, PILON, OR PLATEAU FRACTURES**
- This is a temporary frame designed for rapid distraction and gross reduction used for all types of tibial pathology.
  - A proximal centrally threaded transfixion pin is applied one fingerbreadth proximal to the tip of the proximal fibula. It is inserted from lateral to medial (TECH FIG 7A,B).
  - Alternatively, this pin can be placed into the distal femur at the level of the midpatella along the midlateral condyle of the femur.
  - A second transfixion pin is placed through the calcaneal tuberosity, similar to the ankle-spanning frame described above.
- Two long connecting bars are then attached to the pins on each side of the leg.
  - Longitudinal traction is applied and a gross reduction is achieved.
  - In some circumstances, a third pin is placed into the tibial shaft and attached to one of the longitudinal bars by a third connecting bar (TECH FIG 7C,D). This is done to add stability to this very simple frame.
**TECH FIG 7 • A,B.** Application of spanning two-pin fixator “traveling traction” with attachment of medial and lateral bars. This is used as a very temporary frame to stabilize a variety of conditions. **C,D.** Two-pin fixator used to stabilize a severe plateau fracture. A third pin was inserted into the distal third of the tibia to provide additional stability. The frame is prepared directly into the operative field at the time of secondary surgery to definitively stabilize the fracture using a medial buttress plate.

**PEARLS AND PITFALLS**

**Pin placement location**
- Areas of soft tissue compromise, open wounds, and occult fracture lines as identified on CT scans should be avoided. This prevents any associated pin tract infection from involving the fracture site. The frame must be constructed and applied to allow for multiple débridements, subsequent soft tissue reconstruction, and definitive secondary internal fixation conversions. Thus, the pins must be placed away from the zone of injury to avoid potential pin site contamination with the operative field.

**Pin insertion technique**
- Adequate skin release is provided to avoid tethering or bunching of soft tissues around pins. Pins are overwrapped with small gauze wrap to provide a stable pin–skin interface and to avoid excessive pin–skin motion and development of tissue necrosis and infection.

**Temporary frames require adjunctive splinting of knee, leg, ankle, and foot.**
- Temporary spanning frames are not excessively rigid and require additional splinting to maintain the foot in neutral and to avoid the development of equinus contractures.

**POSTOPERATIVE CARE**

- A compressive dressing should be applied to the pin sites immediately after surgery to stabilize the pin–skin interface and thus minimize pin–skin motion, which can lead to the development of necrotic debris.
- Compressive dressings can be removed within 10 days to 2 weeks, once the pin sites are healed.
- If appropriate pin insertion technique is used, the pin sites will completely heal around each individual pin. Once healed, only showering, without any other pin cleaning procedures, is necessary.
- Removal of a serous crust around the pins using dilute hydrogen peroxide and saline may occasionally be necessary.
- Ointments should not be used for pin care. They tend to inhibit the normal skin flora and alter the normal skin bacteria and may lead to superinfection or pin site colonization.
- If pin drainage does develop, pin care should be provided three times per day.
This may also involve rewrapping and compressing the offending pin site in an effort to minimize the abnormal pin–skin motion.

Following a standardized protocol that involves precleaning the external fixator frame, followed by alcohol wash, sequential povidone–iodine preparation, paint, and spray with air drying followed by draping the extremity and fixator directly into the operative field, additional surgery can be safely performed without an increased rate of postoperative wound infection.

Definitive treatment with an external fixator demands closed scrutiny of the radiographs to ensure that the fracture has completely healed before frame removal. Various techniques have been described, including CT scans, ultrasound, and bone densitometry, to determine the adequacy of fracture healing.

In general, the patient should be fully weight bearing with minimal pain at the fracture site. The frame should be fully dynamized such that the load is being borne by the patient’s limb rather than by the external fixator.

OUTCOMES

Staged management of high-energy tibial plateau and tibial pilon fractures using spanning external fixation to allow the recovery of soft tissues has reduced the overall rates of soft tissue complications. With secondary plating procedures after soft tissue recovery, infection rates have been reported to be less than 5% for complex plateau fractures and less than 7% for complex pilon fractures.

No severe complications related to the temporary external fixator alone have been reported.

Immediate external fixation followed by early closed interlocking nailing has been demonstrated to be a safe and effective treatment for open tibial fractures if early (less than 21 days after injury) conversion to intramedullary nailing is performed.

Early soft tissue coverage and closure is the primary determinant of delayed infection, highlighting the need for effective soft tissue management and early closure of open injuries.

Definitive treatment of open tibial fractures with external fixation has a higher rate of malunion compared with intramedullary nailing. No difference in union rates is noted. Slightly higher rates of infection are noted in the external fixation group.

The severity of the soft tissue injury rather than the choice of implant appears to be the predominant factor influencing outcome. External fixation is preferentially used in patients with the most severe soft tissue injuries or wound contamination.

COMPLICATIONS

Wire and pin site complications include pin site inflammation, chronic infection, loosening, or metal fatigue failure.

Minor pin tract inflammation requires more frequent pin care, consisting of daily cleansing with mild soap or half-strength peroxide and saline solution.

Occasionally an inflamed pin site with purulent discharge will require antibiotics and continued daily pin care.

Severe pin tract infection consists of serous or seropurulent drainage in concert with redness, inflammation, and radiographs showing osteolysis of both the near and far cortices.

Once osteolysis occurs with bicornital involvement, the offending pin should be removed immediately, with débridement of the pin tract.

Late deformity after removal of the apparatus usually presents as a gradual deviation of the limb. This often occurs if the patient and surgeon become “frame weary,” which results in frame removal before healing is complete.

One should always err on the conservative side and leave the frame on for an extended time to ensure that the fracture has healed.

When late deformity occurs, it usually has an unsatisfactory outcome unless collapse is detected early and the frame is reapplied.

If untreated, the resulting malunion requires secondary osteotomy procedures.

Early detection of delayed union often requires adjunctive bone grafting for previously open shaft fractures.

REFERENCES

Intramedullary nailing (IMN) techniques typically are used for closed and open displaced diaphyseal tibial fractures. With additional techniques described in this chapter, the indications for intramedullary nailing can be extended to proximal and distal metaphyseal tibia fractures, including those associated with simple articular involvement.

ANATOMY

The triangular-shaped proximal tibia is most narrow medially, and the proximal medial cortex tibia is obliquely oriented to the frontal plane. The medullary canal of the tibia exits at the margin of the lateral articular facet. As a result of this complex proximal anatomy, there is less sagittal plane space for an intramedullary nail within the tibia metaphysis with a medial or central insertion path, and the anterior medial metaphyseal cortex can deflect the nail and create a valgus deformation. Thus, lateral start sites are more favorable.

The patellar tendon inserts on the tibial tubercle and extends the proximal fracture segment in proximal fracture patterns. This displacement is accentuated with further flexion of the knee, which typically is required to attain the proper starting point for intramedullary nailing (FIG 1A).

Gerdy’s tubercle—the origin of the anterior compartment muscles and insertion site of the iliotibial band—is palpable along the proximal lateral tibia. The anterior compartment muscles and the iliotibial band contribute to shortening and the valgus deformity that is typically seen with proximal fractures.

The anterior tibial crest corresponds to the vertical lateral surface of the tibia. When it is palpable, it is an excellent reference for the anatomic axis and nail path (FIG 1B).

The anteromedial tibial surface is subcutaneous and often is the site of traumatic open wounds.

The anterior neurovascular bundle and tibialis anterior tendon are at risk with anterior-to-posterior distal interlocking screw paths; internal rotation of the nail may decrease the risk of iatrogenic nerve injury (FIG 1C).

The Hoffa fat pad and intermeniscal ligament are commonly injured during nail insertion, especially during lateral parapatellar and patellar tendon-splitting approaches.

PATHOGENESIS

Tibial shaft fractures may occur from high-energy mechanisms of injury, as when a pedestrian is struck by a motor vehicle. Many fractures, however, result from low-energy mechanisms such as simple falls in elderly patients or those with poor bone quality, or sports-related injuries (usually in soccer players) in young patients.

In this low-energy fracture group, elderly patients are more likely to have comminuted and open fractures due to simple falls.

NATURAL HISTORY

The long-term outcome of tibial malunion is not clearly defined in the trauma literature.

A weak association is seen between a tibial shaft fracture malunion and ipsilateral knee and ankle arthritis.

Knee pain is reported in up to 58% of cases after intramedullary nailing. This pain typically is anterior, associated with activity, and exacerbated by kneeling activities.

Knee pain improves in about 50% of patients after hardware removal.

Attempts to detect a correlation between start sites and knee pain have been inconclusive, and a comparative evaluation between traditional start sites and newer start sites (ie, suprapatellar) has yet to be completed.

PATIENT HISTORY AND PHYSICAL FINDINGS

Understanding the mechanism of injury and the environment in which the injury occurred is important for evaluating a patient’s risk for associated injuries and compartment syndrome. In open fractures, it can help determine the choice of prophylactic antibiotic therapy.

All patients who sustain tibial shaft fractures from high-energy mechanisms should undergo standard advanced trauma and life support (ATLS) protocol to have a thorough examination for life- and other limb-threatening injuries. Seventy-five percent of patients with open tibia fractures have associated injuries.

To evaluate a patient’s risk for potential complications, other medical conditions should be investigated, eg, a history of diabetes mellitus, renal disease, inflammatory arthropathies, tobacco use (which increases healing time by up to 40%), and peripheral vascular disease.

It also is important to find out about the patient’s normal activities and employment requirements to give them a reasonable expectation for when they will be able to resume those activities.

Pain at the fracture site, swelling, and deformity are common findings in patients with tibial shaft fractures.

A thorough examination of the skin is important to avoid missing open fracture wounds.

Evaluation of the soft tissue envelope for abrasions, contusions, and fracture blisters can help determine whether definitive treatment can be done primarily or if a staged or delayed approach is required.

A thorough neurovascular examination is critical to avoid the devastating complications associated with compartment syndrome, which can occur in both closed and open fractures (see Chap. TR-17).

IMAGING AND OTHER DIAGNOSTIC STUDIES

Full-length (orthogonal) anteroposterior (AP) and lateral plain radiographs are necessary to adequately evaluate the
tibia and fibula for concurrent fractures or dislocation and any preexisting deformity or implants.

- Orthogonal radiographic views of the knee and ankle are required to rule out articular involvement.
- Axial CT scan can be used for proximal and distal fractures to rule out intra-articular fracture extension.
- Nondisplaced fracture lines are common.
- Gunshot wounds may merit CT evaluation to rule out intra-articular bullet fragments.
- MRI is not useful for most diaphyseal or metadiaphyseal fractures.
- Ankle–brachial or ankle–arm indices after fracture reduction should be used to rule out vascular injuries in severely displaced fractures or fractures with severe soft tissue injury. Values of less than 0.9 may be indicative of vascular injury, requiring further investigation.
- Compartment pressure evaluation with a commercially available hand-held single-stick monitor or with a side-ported catheter connected to a pressure monitor (using the arterial line set-up) is indicated in patients who have severe or increasing swelling and are not able to comply with physical examination and questioning (see Chap. TR-17).
- Observe for early signs of compartment syndrome in all patients with tibial diaphyseal fractures.
- Open fracture does not preclude development of compartment syndrome.
- Measure the pressure difference between the diastolic pressure and the intracompartmental pressure—a differential value of less than 30 mm Hg is considered an indication for a four-compartment fasciotomy.

**NONOPERATIVE MANAGEMENT**

- Nonoperative management is indicated in ambulatory patients for closed and open fractures that do not require flap coverage and that do not present with excessive initial shortening or unacceptable angulation when a cast is applied (FIG 2).
An intact fibula with an axially unstable fracture pattern (i.e., short oblique, butterfly, comminuted) is at risk of shortening and varus and is a relative contraindication to nonoperative management. A higher rate of malunion and nonunion with nonoperative management is seen in higher-energy fractures. Joint stiffness, especially hindfoot, is common with all forms of prolonged immobilization. Initial treatment includes 2 weeks of a long leg splint, then a long-leg cast for 2 to 4 weeks. When the initial swelling has subsided, the patient is graduated to a patellar tendon or functional brace with weight bearing allowed and encouraged. Radiographs are evaluated at 1- to 2-week intervals over the first month of treatment to confirm maintenance of acceptable alignment.

### SURGICAL MANAGEMENT

#### Classification and Relative Indications
- Tibia fractures usually are classified according to the AO/OTA classification (Table 1).
- Several relatively well-accepted indications and contraindications have been established for the intramedullary nailing of tibia fractures (Table 2).
- A thorough evaluation of the patient’s soft tissue envelope will determine when the patient can proceed with definitive fixation.
- Complete orthogonal radiographs of the entire tibia and fibula are important to determine whether the patient’s intramedullary canal is large enough to accommodate an intramedullary nail and identify any pre-existing deformity that may preclude nail placement. Complete radiographs also identify any proximal or distal articular involvement.
- Preoperative measurement of the intramedullary canal and the length of the tibia will help determine which size nail can be used.
- The lateral radiograph is the most accurate to use for measuring the appropriate nail length.
- Measuring the narrowest diameter on the AP and lateral views will determine the appropriate nail diameter and whether intramedullary reaming will be necessary.
- Orthogonal radiographs of the uninjured tibia can be used as templates for determining the appropriate length, alignment, and rotation in comminuted fractures or open fractures with bone loss.

#### Positioning
- Supine positioning is standard.
- A fracture table can be used with boot traction, calcaneal traction, or an arthroscopy leg holder that supports the leg and provides mechanical traction when no assistants are available. However, knee hyperflexion is difficult, and the guidewire insertion angle is suboptimal for proximal fractures (FIG 3A).
- The patient is placed on the radiolucent table in one of the following positions:
  - Supine with the leg free (FIG 3B)
  - Mechanical traction is helpful to achieve reduction when the leg is draped free (FIG 3C,D).
  - The proximal posterior transfixion pin (FIG 3E) is inserted medial to lateral and parallel to the tibial plateu.
  - The distal transfixion pin (FIG 3F) is inserted parallel to the plafond and inferior to the projected end of the nail.
  - Supine with the leg flexed over a bolster or radiolucent triangle (FIG 3G)
  - Maximizing knee flexion makes it easier to attain a start site and to determine the optimal insertion vector (which approaches a parallel path with the anterior tibial border).
  - Semi-extended position
  - For proximal fractures, extending the knee to 20 to 30 degrees of flexion counters the pull of the patellar tendon.
